With severe lesions of the spinal cord, sweating is excessive on the paralysed parts of the body. If not evident it may be excited by cutaneous stimuli or by the injection of a small dose of pilocarpine (gr.  $\frac{1}{8}$ ), and the level of a spinal lesion may be determined by this means by an observer who is familiar with the cutaneous segmental distribution.

#### SURFACE ANATOMY

If the cord is to be exposed at the level of the affected segments their relation to the spinous processes of the vertebræ must be known. The segmental localisation of a lesion having been obtained, the desired segment can be found as follows: in the cervical region of the cord, deduct one from the number of the segment—the sixth cervical segment is at the level of the fifth cervical spine; in the upper half of the thoracic cord, deduct two—the fifth thoracic segment is at the level of the third thoracic spine; and down to the first lumbar segment, deduct three—the first lumbar segment is at the level of the tenth thoracic spine. The remaining segments of the cord are shorter and so are farther separated from their corresponding vertebræ. The third lumbar segment is approximately at the level of the eleventh dorsal spine,

and the first sacral segment at the level of the twelfth. The cord terminates just above the level of the first lumbar spine.

#### LOCALISATION BY MYELOGRAPHY

When the existence of a compressive lesion of the cord or its exact site is in doubt, great help may be obtained by injecting into the thecal canal a fluid substance which is opaque to radiography. If 1 or 2 ml. of Myodil or other opaque medium be injected through the occipito-atlantoid ligament into the cisterna magna of the sub-arachnoid space, it falls rapidly to the site of obstruction, where it is arrested, wholly or partially, and can be seen on the radiographic screen or film, in relation to the vertebrae. A safer procedure is to inject the Myodil by lumbar puncture and then, making use of a tilting X-ray table, to tilt the patient so that the oil runs towards his head. Even when the lesion is as high as the cervical region, this manoeuvre is satisfactory, though some discomfort may be caused to the patient by prolonged tilting. The oil will run more rapidly within the theca if it is heated to just above body temperature by immersion of the phial in warm water for 15 to 20 minutes before injection.

#### GENERAL MANAGEMENT OF PARAPLEGIA

In all cases of severe paraplegia from spinal cord lesion in which sensory and sphincter functions are also impaired or lost, whatever the nature of the lesion, there are certain general principles of treatment. The patient should be nursed on a fracture bed, with an air, water or foam rubber mattress. The back should be attended to 4-hourly, first washed with soap and water, then carefully dried, rubbed with surgical spirit or Eau-de-Cologne, and powdered. These measures harden the skin and make it less likely to break down under the constant pressure of the body-weight. The patient's position should be changed at intervals of not more than 3 hours and he should be made to lie on his face for at least 6 hours in 24 in order to prevent the development of sacral bed-sores. When there is incontinence of urine, as far as possible care should be taken to prevent the skin from becoming wet and sodden, and the toilet of the anus after defaecation should be careful and thorough. There are various remedies for the sacral or trochanteric bed-sore when it develops. Separation may be hastened by wet dressing of eusol, or sometimes by fomentations, though the latter should be used with caution. The ulcer is packed with eusol gauze, or with an ointment of zinc oxide and castor oil. When it is clean and healing begins, it may sometimes be hastened by dressings of gauze soaked in red lotion. The heels should also be carefully watched for the appearance of the hæmorrhagic blisters which herald the development of a sore. Rings for the heels may avert them, and air rings for the sacrum may also be needed.

*Rehabilitation of the paraplegic.*—Experience gained during the War of 1939-1945 has gone far to improve the lot of paraplegics suffering from irreparable but solitary lesions of the spinal cord, particularly young subjects with traumatic lesions.

Bed-sores, even of large dimensions, can be caused to heal by active treatment, as described by Guttman. Supra-pubic cystostomy and tidal drainage of the bladder may gradually be replaced by the development of satisfactory automatic emptying, which permits the use of a urinal. Contractures and deformities can be prevented, or where necessary corrected. Physiotherapy and training directed to the healthy muscles may enable the patient to replace to a great extent the functions of the paralysed parts, as well as overcoming the gravitational effects in the circulation, which are a conspicuous feature of thoracic cord lesions.

Finally, occupational therapy, both prevocational and vocational, in specialised spinal centres and mental readjustment can enable these patients to a remarkable degree to resume their places as active members of the community.

## TUMOURS OF THE SPINAL CORD

**Synonym.**—Intramedullary Tumours.

**Ætiology and Pathology.**—Tumours of the spinal cord while uncommon, are not rare, and are encountered at all ages. According to Kernohan's statistics the ependymoma, a tumour arising from the cells of the ependyma of the central canal, is the commonest type, forming about half of the total number. Tumours of this variety are demarcated from the nervous tissue of the cord, and although centrally placed are capable of surgical removal. They arise most frequently in the cervico-thoracic region and in the filum terminale. Various types of gliomata form the remainder of the total, the glioblastoma being the most common; all the tumours of this group are of an invasive character, devoid of any definite demarcation, and therefore incapable of being removed by operation without gross damage being done to the cord. In addition to the tumours arising from the tissues of the cord medulloblastomata and oligodendrogliomata may be found on the surface of the cord as seedling metastases from cerebral and especially cerebellar tumours. Various types of hæmangioma are also found.

**Symptoms.**—In the case of any patient presenting the signs of a local lesion of the spinal cord of gradual onset the possibility of an intramedullary tumour should be kept in mind.

The symptoms often start unilaterally, with weakness and stiffness of one leg, and at a slightly later stage a partial Brown-Séquard syndrome is not uncommon. At all stages dissociated sensory disturbances are common on account of different degrees of involvement of sensory tracts. Root pains are unusual, but local muscular wasting, corresponding to one or several consecutive segments, is frequently present. Sphincter disturbances occur at a relatively early stage.

The cerebrospinal fluid contains a moderate excess of protein, and some excess of globulin. Queckenstedt's test does not indicate any blockage in the spinal theca until the tumour has reached such a size that it occupies most of the width of the theca. Unless the tumour is at an advanced stage, there may be no obstruction to the passage of Myodil, and even at a late stage the obstruction may be only partial. The expanding mass within the spinal theca may cause thinning of the pedicles of several consecutive vertebræ, which may be apparent in the radiograph, and in consequence of the thinning the interpeduncular distance on each affected vertebra is increased.

**Diagnosis.**—This has to be made from (1) other forms of spinal cord disease which produce paraplegia of gradual onset, and (2) compression of the cord from without. Of the former, disseminated sclerosis is usually the most difficult to exclude, and is the disease to which the symptoms of spinal tumour are most often wrongly attributed. The diagnosis of disseminated sclerosis is rarely justified unless there is evidence of several lesions in the central nervous system, and if after careful examination of the whole nervous system all the signs and symptoms can be attributed to a single spinal lesion, the probability of tumour is greatly increased. Secondly, with tumour, the exacerbations and remissions of disseminated sclerosis do not occur. Finally, in a case of tumour the cerebrospinal fluid may show a considerable increase of protein; a moderate increase, however (·06 per cent. or less), does not help in the differentiation. It should also be borne in mind that the spinal fluid in an active case of disseminated sclerosis occasionally gives a "paretic" type of curve with Lange's colloidal gold test, which does not occur in the case of tumour. Cases of supposed disseminated sclerosis beginning after the age of 45, especially in males, should be regarded with the greatest suspicion. The diagnosis may be particularly difficult in cases of hæmangioma of the cord, because in many of these there is evidence of two spinal lesions.

Localised spinal syphilis may also closely simulate intramedullary tumour, but such cases are quickly recognised if the Wassermann reaction is performed on the cerebrospinal fluid and blood as a routine measure.

The diagnosis between intramedullary tumour and compression of the cord from without (e.g. by a meningeal tumour, or a neurofibroma) cannot usually be made with confidence on clinical grounds. Search should first be made for evidence of those conditions which are known to cause compression. Queckenstedt's test may, of course, indicate obstruction in the theca, but in many cases at the stage at which diagnosis is called for it gives an indefinite result, and radiographic investigation with Myodil is then required. If this reveals no obstruction, or if the picture obtained indicates a fusiform expansion of the cord with a little of the oil passing down at the sides of it, the diagnosis of intramedullary tumour may be accepted. In many cases the final diagnosis is made only by exploratory operation.

**Treatment.**—Many ependymomas have been successfully removed by skilled neuro-surgeons, the cord having been incised between the posterior columns. If exploratory operation reveals a glioma or evidence of a hæmangioma, surgery can do no more to benefit the patient, and the treatment thereafter is that of paraplegia in general. Radiotherapy is ineffective.

## COMPRESSION OF THE SPINAL CORD

In compression, the lumen of the spinal canal is reduced in a small part of its length and the spinal cord is injured at this point, either directly by pressure or indirectly by interference with its blood supply. Nearly all the extramedullary lesions of the cord come under this heading. Except in cases of collapse of a vertebral body such as may occur in malignant disease, compression is in general a slow process, although in a number of cases the symptoms come on rather abruptly. A sudden process, such as fracture-dislocation of the spine, causes laceration rather than compression of the cord.

Clinically, compression is characterised by a combination of two sets of phenomena, namely, local or root symptoms in the regions supplied by the roots arising from the cord at the level of the lesion; and remote or cord symptoms due to interruption of the conducting paths in the white matter. Obstruction of the spinal theca may be inferred if Queckenstedt's test (see p. 1378) is positive. In addition, complete or partial obstruction is associated with an increase of protein in the fluid below the obstruction, and Froin's syndrome (see p. 1379) may be present. In most cases the fluid shows a slight degree of xanthochromia. Radiographic examination after injection of Myodil into the theca (see p. 1533) confirms or reveals the site of the obstruction, and the outline of the filling defect may give a valuable clue to its nature.

Compression of the spinal cord may be the result of (1) conditions arising within the theca, the most important of these being meningeal tumours, neurofibromata and arachnoiditis; and (2) lesions compressing the theca and subsequently the cord. Of the latter, the most important are vertebral diseases, especially tuberculous disease of the spine and secondary carcinoma; also common is a protruding intervertebral disc; and rarer causes are extra-theal abscess, Hodgkin's disease, Paget's and other forms of bone disease.

### I. INTRATHECAL COMPRESSION

#### MENINGEAL TUMOURS

Though fibroma and sarcoma are occasionally found, for practical purposes the "meningioma", or endothelioma of the dura, is the only common tumour arising from the spinal meninges.

**Ætiology and Pathology.**—The meningioma is a firm, oval, pinkish tumour of smooth or nodular outline. When impregnated with calcareous deposits the term "psammoma" was applied to it, and it may become so calcified as to be discernible on a radiograph of the vertebral column. The incidence of these tumours is mainly between 30 and 60 years of age, and they affect women much more often than men. Their common site is in the thoracic region and they usually lie posterior to the spinal cord.

**Symptoms.**—Pain of root distribution and of variable severity is usually the first symptom. It is aggravated, typically, by coughing, sneezing or straining. This is followed after some time by spastic paralysis of slow onset and steady uninterrupted progress, affecting first one leg and then the other, the combination and especially the course of these symptoms being almost pathognomonic. Sensory signs of similar slow course accompany the motor signs, or follow them after a brief interval. The sense of position may be the first to be disturbed, and give rise to unsteadiness in walking and standing. By the time the patient comes under observation the cerebro-spinal fluid shows considerable increase in its protein content and in the globulin fraction, and Queckenstedt's test is positive. If the tumour is in the cervical region, as is unusual, all the foregoing changes are less intense.

Radiographic examination may reveal an outline of the tumour at the level determined clinically, or, more often, it shows some change in the shape of the pedicles of the vertebral arches, or an increase of the interpeduncular distance. Myodil introduced into the theca is held up, and its border in contact with the obstruction displays the outlines of the surface of the tumour.

**Diagnosis.**—With such manifestations the diagnosis of meningioma is most probable, but the diagnosis from other forms of intrathecal obstruction is not certain until the tumour is seen at operation. The diagnosis from extra-theal compression is usually easier. With spinal caries root pains are rarely so severe, signs of bone disease are rarely absent, and the paralysis is usually bilateral from the beginning and is severe by the time sensory loss develops. The distinction from vertebral new-growth is generally made or confirmed by radiographic examination, but may for a time be impossible when bone symptoms and radiographic signs are absent.

**Course and Prognosis.**—The growth is often extremely slow. Root symptoms may precede paralysis by months or even years, and the weakness may increase gradually for several years before walking becomes impossible. In the absence of operation it progresses eventually to complete motor, sensory and sphincter paralysis, possibly with paraplegia in flexion. Most patients with simple tumours come to operation during the second year after the onset of the first symptom. The prognosis for recovery of power after removal of the tumour depends in part on the duration of the weakness in the lower limbs. Complete recovery may be expected if it has not lasted more than a year, and if sphincter control has not been lost. Recovery from severe paralysis takes from 5 to 9 months. When the paralysis is of longer duration, recovery, though gratifying, is rarely complete. Nevertheless, full return of power has been seen after 3 years of severe paralysis.

**Treatment.**—This is obviously surgical. The mortality after operation for the removal of simple tumours is low in skilled hands. During the recovery stage following removal of the tumour, the treatment after the operation wound has healed is that of spastic paraplegia in general (p. 1533).

#### NEUROFIBROMATA

**Ætiology and Pathology.**—Neurofibromata within the spinal theca affect both sexes and occur mostly in early middle life. They arise on the spinal nerve roots, and may be solitary or multiple. In cases of neurofibromatosis the occurrence of small neurofibromata on many of the lower spinal roots is the rule, although they

may not give rise to severe symptoms. A neurofibroma may be situated partly within and partly outside the vertebral canal, the constriction at the intervertebral foramen giving the tumour a dumb-bell shape. Histologically the intrathecal neurofibroma has a structure similar to that of the acoustic neuroma (see p. 1382).

**Symptoms.**—A neurofibroma compressing the spinal cord is apt to give rise to unilateral symptoms, and to the Brown-Séquard syndrome. Root pains may be severe, and in some cases there are spasms of intense pain on the opposite side of the body below the level of the tumour resulting from irritation of the spino-thalamic tract by the growth.

**Diagnosis.**—The unilateral nature of the spinal signs may suggest the nature of the tumour. Also, neurofibromata cause a great increase of protein in the cerebrospinal fluid; findings above 1 per cent. are common in the lumbar fluid, and even in the fluid above the tumour the protein content is raised. The fluid withdrawn at lumbar puncture may be yellow. Queckenstedt's test and examination with Myodil disclose complete or partial obstruction of the theca. Radiographic examination of the spine shows in many cases enlargement of the intervertebral foramen through which the affected nerve root emerges, and the Myodil picture may show the lateral situation of the obstructing mass.

**Prognosis and Treatment.**—For the solitary neurofibroma these are similar to those of a spinal meningioma. When multiple neurofibromata are present the prognosis is less favourable, although the removal of a single tumour may completely relieve the spinal compression.

#### ARACHNOIDITIS

**Synonym.**—Meningitis Serosa Circumscripta.

**Ætiology.**—As a result of a low-grade inflammation of the arachnoid membrane, adhesions occur within it and give rise to cystic formations containing cerebrospinal fluid, or the membrane, thickened and fibrous, may become bound down on to the spinal cord. Such arachnoiditis follows injury (perhaps as a reaction to hæmorrhage), or is a consequence of generalised infectious diseases, or it may follow meningitis.

**Symptoms.**—In the course of a year or several years, the cyst or contracting membrane may cause slowly increasing pressure on the cord. Root pains are seldom pronounced, but muscular wasting may occur, corresponding to the site of the maximal local incidence of the arachnoiditis. The tract signs are usually limited to gradually increasing spasticity of the lower limbs, but sensory changes, with a definite level, may develop. Pressure measurements at the time of lumbar puncture may reveal complete or partial obstruction of the theca, and the Myodil picture may show an appearance of guttering, the opaque fluid being broken into droplets among the arachnoid adhesions.

**Prognosis and Treatment.**—In the case of a cyst its removal by operation may bring about great improvement in the patient's clinical condition. The sites of adhesion may be difficult to see, and if the cyst be opened inadvertently during operation, the only evidence of its former presence is flattening of the cord and of the nerve-roots at the level of the expected lesion. Sometimes the position of the cyst can be inferred from the absence of normal pulsation below that level. When the membranes are punctured in this position, fluid escapes under pressure and the pulsations reappear. Later, symptoms may recur, or, in spite of operation they may progress as a result of the adhesive process.

#### 2. EXTRATHECAL COMPRESSION

With extrathecal compression, the pressure on the spinal cord is apt to be more uniform, and the manifestations have in consequence a greater tendency to be equal

on the two sides, especially in the lower limbs. This is, however, no more than a rule of thumb and there are many exceptions to it. As long as the compression is relatively slight, motor tracts are more affected than sensory, and consequently with the more slowly progressive conditions, weakness and spasticity of the lower limbs may precede sensory disturbances by a long period.

#### TUBERCULOUS DISEASE OF THE SPINE

**Synonyms.**—Spinal Caries; Pott's Disease.

This disease is the most frequent cause of slow compression. It occurs most often in children, but is common in adults, and may begin late in life. Signs of injury to the cord develop in about 1 case in 20, and are usually preceded by obvious deformity of the spine, but in many cases they appear before disease of the bone is suspected. Rarely paralysis comes on for the first time in an adult who has had a curvature since childhood.

The cord may be damaged by direct pressure of displaced bone, but more commonly by an abscess beneath the periosteum of the diseased vertebrae. In almost all cases the injury is indirect, and results from œdema of the cord, arising from interference with its blood supply by tuberculous granulation tissue, which forms on the outer surface of the dura mater and fills the epidural space (pachymeningitis externa). The functions of the cord may be temporarily deranged for long periods by this œdema, without permanent damage to the nervous tissues; hence, when the disease is cured, the œdema subsides and the cord recovers. In cases of greater severity necrosis of the nervous structures follows thrombosis of the vessels, or prolonged pressure causes atrophy of nerve roots, and complete recovery is impossible.

**Diagnosis.**—When spastic paraplegia develops in a patient who is known to suffer from tuberculosis of the spine, the cause is obvious; but when it precedes the appearance of signs of bone disease, the diagnosis is difficult. In all cases of compression the spine should be examined repeatedly for deformity, tenderness and limitation of movement. If tenderness is found constantly in the same place, and the nervous symptoms are compatible with disease of the underlying segments, disease of the bones is almost certain. In young persons disease of the spine is usually caries, and in adults also caries is not uncommon, but tumours of the spine and aneurysm should be excluded. Severe root pains are rare in spinal caries but are the rule in vertebral new-growth. A radiograph will usually demonstrate the presence and nature of the bone disease.

**Course and Prognosis.**—The course of the bone disease does not always run parallel with the paralysis, and either may alter in severity independently, but if the caries undergoes cure the paralysis usually diminishes. Considering the severity of the paralysis, the prognosis is favourable and astonishing recoveries occur. The outlook is best in young people with disease in the dorsal region. Many recover completely, but more often, especially in adults, recovery, though considerable, is imperfect. So long as the lower limbs remain spastic in the extended position together with exaggerated tendon reflexes the prognosis for complete recovery of power is good; but if the limbs become flexed, if they become flaccid, if the knee- and ankle-jerks are lost, if sensory loss is severe, or if there is wasting in the limbs following damage to lower motor neurones, the outlook is bad. Some patients live for years with severe paralysis, but life is constantly endangered by sepsis from bed-sores, ascending infections of the urinary tract, chest complications and tuberculous disease in other parts.

**Treatment.**—This is to be directed towards curing the bone disease in the hope that cure of the paralysis will follow, and it usually does so. Complete rest on the back and fixation of the spine for many months is the routine treatment and recovery commonly takes about 2 years. Streptomycin and isoniazid should be administered.

as in other forms of tuberculosis. The general condition of the patient is to be improved by fresh air, a liberal diet, cod-liver oil and iron, and great care is to be taken to prevent bed-sores, cystitis and deformities of the limbs. Laminectomy is in general contraindicated, and operative intervention of any kind should only be undertaken by a surgeon who has special experience of this disease. After the bony disease has healed, fixation of the spine by Allbee's operation or a modification thereof is called for in a few cases.

### TUMOURS OF THE VERTEBRAL COLUMN

Vertebral tumours are about twice as common as all the other forms of extra-medullary tumours together, and almost all of them are malignant. Carcinoma is always secondary, and is a frequent and distressing complication of cancer elsewhere. A very small primary carcinoma, *e.g.* of the breast, lung, thyroid or prostate, may produce extensive disease of the vertebrae. Evidence of compression may appear before the existence of the primary growth is suspected, but, on the other hand, such may occur several years after complete removal of the primary growth and may even be the first evidence of a recurrence. Sarcoma, though the commonest form of primary growth, is relatively rare and it begins in the bone or periosteum of the bodies or laminae. Primary sarcomata are sometimes multiple. Secondary sarcoma arises by metastasis from sarcoma elsewhere, or by direct extension from a growth in neighbouring soft parts, *e.g.* of tumours in the mediastinal and retroperitoneal spaces.

The growth of vertebral tumours is usually rapid, and extensive portions of the spinal column may be completely destroyed. The cord is compressed by the growth itself, by displaced bone, or by a process of the growth which invades the spinal canal through an intervertebral foramen. As a rule, the dura mater sets bounds to its inward extension. Benign tumours of the spine are rare. They usually grow forwards, but occasionally an osteoma, or an exostosis, produces signs of compression.

**Symptoms.**—In most cases these are typical of spinal compression. Root pains are usually severe and may be agonising, but occasionally they are absent. Not infrequently the onset of paraplegia is rapid, paralysis developing in the course of 24 or 48 hours. No deformity of the spine is ordinarily apparent, but local tenderness is usual, and radiographic examination reveals bony disease at a level corresponding to it. Lumbar puncture reveals the signs of thecal obstruction.

**Diagnosis.**—When root pains occur in a patient with malignant disease, or from whom a malignant growth has been removed, the diagnosis of secondary growth in the vertebral column is most probable, even though radiographic examination fails at first to reveal any deposits in the vertebral bones. When pains are the first symptom, mistakes are easily made because their root origin is not recognised. Diminished sensibility in the painful area indicates the nature of the pain, and this directs attention to the spine, where tenderness or deformity is discovered. As most vertebral tumours are secondary, the next step is to examine the parts where carcinoma is common, remembering that a small primary growth, *e.g.* in the breast, lung, thyroid or prostate, may give rise to widespread metastases in the bones. In the absence of a history or signs of new-growth in other parts, the diagnosis is founded on the combination of local tenderness or deformity and rigidity of the spine with root or cord symptoms. The severity of the root pains, and their great aggravation by movement, are characteristic.

**Course and Prognosis.**—When sarcoma or carcinoma spreads to the vertebrae from surrounding parts, the duration of the disease is measured in weeks or months, and death is due to the primary condition. In primary sarcoma, and in some cases of carcinoma of the vertebrae, life may be prolonged for a year or two, and death is due rather to complications of the cord disease—bed-sores, cystitis, etc.

**Treatment.**—In many cases of malignant vertebral disease the clinical effects of compression are relieved by extension of the spine, the patient being kept flat in bed with an underlying fracture board. If the paraplegia improves, a plaster spinal jacket can be applied and the patient may begin to get up again. In favourable cases radiotherapy may then be considered. When root pains lead to the discovery of a secondary deposit in the spine in a case in which the primary growth has been removed and there is no evidence of secondary growths elsewhere in the body, radiotherapy should be employed; paraplegia is prevented, the pains are relieved and life is prolonged. In slowly growing primary growths of the vertebrae, laminectomy is indicated in order to relieve pressure, or to prevent pain by cutting sensory roots, or dividing the antero-lateral columns of the spinal cord. The operation is merely palliative but is often followed by considerable temporary recovery.

#### PROTRUDING INTERVERTEBRAL DISK (CERVICAL AND DORSAL)

The protrusion of an intervertebral disk in the cervical or dorsal region is much less common than in the lower lumbar region. The mechanism by which it occurs is the same at all levels; as a result of trauma the cartilaginous annular portion of the disk is ruptured, and the semi-solid nucleus pulposus is then gradually extruded. In most cases the mass is protruded backwards into the vertebral canal, and causes compression of the theca. In the cervical region the degree of compression of the cord which ensues is seldom severe.

The clinical history of the case is that of spastic paraplegia coming on gradually some months after an accident. Progress of the paraplegia is usually slow, and after a time one arm or both arms may become spastic and may show a little muscular wasting. At this stage the condition in most instances becomes stationary. Sensory impairment is seldom demonstrable, but there is usually a zone of hyperalgesia corresponding to the segment just above the level of the lesion. Mild root pains across the shoulders are likely to be attributed to rheumatism. In some cases, however, root pains are the principal manifestation and may be ascribed to brachial neuritis.

Unless there is a close association with a definite accident the diagnosis is always a matter of great difficulty and only occasionally can it be made with confidence. The spinal theca in the cervical region is wide and the degree of obstruction is not sufficient to give a positive result with Queckenstedt's test. After injection of Myodil the hold-up is at best partial, but in favourable cases a filling defect is revealed on the radiograph. While the symptoms are progressing the differentiation from an intramedullary tumour of the cervical enlargement may be impossible, but the history of an accident, and the persistent absence of objective sensory loss, should raise a strong suspicion of a disk lesion, and the eventual arrest of the progress excludes the presence of a tumour. From disseminated sclerosis the diagnosis may be equally difficult, but if it be recognised that all the manifestations are attributable to a single spinal lesion it is unjustifiable to postulate disseminated lesions, and moreover many of the patients concerned are above the age at which disseminated sclerosis is likely to begin.

Some of the cases have been relieved by surgical treatment, and it is only by operation that the diagnosis can be established with certainty. Failing operation, the sufferers remain permanently disabled, but a moderate degree of spontaneous improvement is not unknown. Collars of different types are often prescribed to immobilise the neck and take some of the weight of the head off the cervical vertebrae, but it is doubtful whether the effects obtained compensate for the inconvenience or discomfort.

#### INJURIES OF THE SPINAL CORD

**Ætiology.**—The spinal cord is a delicate structure. Injuries of it occur in the first place in association with fractures and dislocations of the spinal column. The

cord is usually lacerated, and its fibres are torn and its circulation interfered with so that compression, if present at all, plays little part in causing the persisting symptoms and its relief brings about no amelioration. Dislocation of the axis, however, provides possible exceptions to this rule. Transverse lesions of the cord may also result from gunshot wounds. Secondly, disruption of fibres, and laceration of other elements and minute hemorrhages occur within a localised extent of the cervical cord as a result of acute flexion of the neck. The damage is probably the result of the sudden traction exerted on the cord, as flexion of the neck causes the cord to be pulled upwards. When the muscles of the neck are relaxed, a very moderate degree of violence may cause the head to fall forward, producing sudden flexion of the neck and damage to the cord. With greater violence there may be accompanying dislocation or fracture of the cervical vertebrae, but in the typical case the spinal cord is not compressed. Sudden extension of the neck, as in diving accidents, also may cause severe injury of the cord, with or without vertebral dislocation or fracture.

Fracture-dislocation of the vertebral column is most common in the region of the fifth and sixth cervical vertebrae and in the lower dorsal region. Crush fractures of vertebral bodies due to force transmitted longitudinally, as when a patient falls from a height and lands on his feet, usually affect the first lumbar or one of the adjacent vertebrae, and the corresponding lumbar spinal roots or the roots of the cauda equina may be damaged. The roots, being peripheral nerves, are generally believed to have greater power of recovery than the structures within the cord itself.

Fractures of the vertebral arches, pedicles or spines may be caused, particularly by gunshot wounds, and in association with them the spinal cord may be injured in greater or less degree.

**Symptoms.**—A sudden transverse lesion of the spinal cord gives rise at first to a condition of "spinal shock", in which most of the automatic functions of that part of the cord below the level of the lesion are temporarily abolished. If this occurs at a high level, death is usually immediate, but if not, flaccid paralysis of all four limbs results. If the lesion is in the dorsal region the immediate result is a state of acute flaccid paraplegia, with retention of urine due to flaccid paralysis of the bladder wall (detrusor urinæ); in severe cases, all the tendon reflexes and the plantar and abdominal reflexes are at first absent, and there is complete loss of sensory appreciation below the level of the lesion. In some cases the degree of spinal shock is less and the abolition of spinal function is partial.

With the traction injuries of the cervical cord there is seldom the same degree of spinal shock, but temporary paralysis may be considerable; sensory loss is usually partial, and some or all of the reflexes are preserved. Retention of urine is in most instances a matter of a few hours. Paralysis of the hands, with relative sparing of the upper arms, is not infrequent in these cases. As the fifth cervical segment is often involved in the lesion, the supinator jerk, which depends on this segment, is often abolished, but the flexion reflexes remain, and tapping of the supinator tendon produces reflex flexion of the fingers. This is called "inversion of the supinator reflex". The fibres of the cervical sympathetic (as they descend in the cord to emerge with the first dorsal root) are often involved in the lesion, and in consequence there may be contraction of the pupil and a slight degree of ptosis of the upper eyelid on one or both sides. At a later stage, when the lower limbs have largely recovered, wasting becomes apparent in the hands and forearms, and the case presents a superficial resemblance to one of amyotrophic lateral sclerosis, but the history of accident, the presence of sensory disturbances and such features as the absence of the supinator jerks and signs of disturbance of the sympathetic nervous system should help to make the distinction (see p. 1556).

**Course and Prognosis.**—In incomplete and mild cases, as spinal shock passes off, the reflexes begin to return. Retention of urine persists for a variable time, and if not prevented by catheterisation, overflow incontinence ensues. The Babinski reflex

appears, and is coupled after a time with withdrawal reflexes of the lower limbs. Later, the tendon reflexes return and a variable degree of sensory and motor recovery may take place. In severe cases this does not happen and the condition remains one of complete physiological interruption of the cord at the site of the lesion. After an interval the lower limbs may become the seat of frequent flexor spasms, and a state of paraplegia in flexion may follow. Any stimulus applied below the level of the lesion may then give rise to violent flexion spasms in the legs, contraction of the abdominal wall and extrusion of urine from the bladder—the “mass reflex” of Head and Riddoch. In the great majority of those cases in which the cord is completely divided, the paralysed muscles remain entirely inert and the only evidence of reflex activity is the development of automatic function of the bladder.

In severe cases, the outlook is always extremely grave. With high cervical lesions, death, if not immediate, may occur within a few hours from respiratory paralysis. With lesions at lower levels death is liable to take place within a few weeks or months, from bed-sores or infection of the urinary tract. The cases of less severe injuries of the cervical spine usually make good recoveries. Wasting and weakness may be left in the hands, and sensory disturbances, particularly of a subjective nature, may persist and affect one side of the body or both sides.

**Treatment.**—Cervical dislocation should be reduced under general anaesthesia, and subsequently a plaster collar should be applied to the neck in order to prevent undue mobility until the damaged ligaments have healed. In cases of cervical fracture, a collar should also be applied, because further displacement may occur during sleep or under other conditions of muscular relaxation.

In cases of fracture of the spinal column with injury of the cord, open operation is usually contraindicated. Fracture of the vertebral arches, on the other hand, may call for operation and the removal of bony fragments from the spinal canal. Pressure on spinal roots is usually relieved by the Watson Jones method of treating spinal fractures.

The further treatment of injuries of the spinal cord is that of acute paraplegia (see p. 1533), and in no condition is the most careful nursing and skilled medical supervision more urgently called for. In general the retention of urine is best treated by immediate supra-pubic cystotomy, but if the nursing conditions are ideal and there is good prospect of recovery, tidal drainage through an indwelling catheter may be preferable. The bowels are best controlled by regular enemata.

## ACUTE TRANSVERSE MYELITIS

**Ætiology.**—The condition is rare during childhood, and mostly occurs during the first half of adult life. The sexes are affected equally. In most cases the cause cannot be determined. While a number are syphilitic, syphilis has long ceased to be the most frequent cause.

**Pathology.**—The cord appears healthy except in a short portion of its length comprising one or two segments. The lesion is most frequently situated in the lower half of the dorsal region, and at its site the cord shows intense signs of disease and may be wholly or partly diffuent. In some microscopic sections of the affected segments no normal spinal tissue may be found, and in others, though elements are spared in an irregular fashion, nearly every portion exhibits some pathological change. The adjoining segments are affected in lesser degree, and elsewhere the cord is healthy. Unless all the elements are necrotic there is evidence of inflammatory reaction in the diseased portions. There is no evidence of primary arterial or venous thrombosis, but intense congestion of vessels and minute points of hæmorrhage may be present. In the syphilitic cases there is intense cellular infiltration within the affected portion

of the cord and in the meninges around it, and some small vessels may be thrombosed, but the lesion does not appear to be primarily thrombotic (see p. 1469).

**Symptoms.**—In the non-syphilitic cases, there may be malaise and a slightly raised temperature and sometimes pain of "root" type at the level of the lesion for a few days before the onset of paralysis. These symptoms are followed by weakness of one or both legs, and paralysis may be complete from the waist down within 24 or 48 hours; in other cases, it is complete in an hour or two; in others, though remaining incomplete, it may reach its full intensity in that time; while in still other cases, the onset is "apoplectic", i.e. the patient feeling some weakness, sits down, and within a few minutes is completely paraplegic.

In the syphilitic cases, pain in the back frequently precedes the onset by several hours or a day or two.

If the patient is seen soon after the onset he usually shows complete motor and sensory paralysis from the waist down, with flaccidity of the muscles and loss of reflexes; retention of urine is present and may have gone on to overflow incontinence. If some power of voluntary movement or some sensation is preserved, some of the reflexes usually persist too. There may be from the first a zone of hyperæsthesia at the upper limit of the paralysis, and later a "girdle sensation" may develop at this site. While the limbs are flaccid and sensation is absent, bed-sores may develop with great rapidity, and in the paralysed bladder intense cystitis may occur. The patient may die in the acute stage as the result of these complications. More often sensation and the reflexes return after a few weeks, and in course of time spasticity develops in the limbs, with a variable amount of voluntary power. There may be a partial Brown-Séquard syndrome. Remarkable recovery may occur in the course of many months, but even then considerable disability usually persists. In other cases there is no return of power, and the bedridden patient succumbs in a few months to intercurrent disease.

**Diagnosis.**—The Wassermann reaction, both in the blood and in the spinal fluid, should always be done, with the knowledge that the latter may give a negative result in syphilitic cases, even when cellular increase is present. Queckenstedt's test should also be done at the time of lumbar puncture, in order to exclude conditions of thecal block. Poliomyelitis is excluded by the presence of severe sensory loss. It may not be possible to make the differential diagnosis from hæmorrhage into the substance of the cord, but the latter is usually associated with more pain and, after the first acute stage is over, with a syringomyelic type of sensory loss. Angioma of the cord usually gives rise to less acute paralysis coming on with less constitutional disturbance.

**Treatment.**—The treatment consists of good nursing, with the most careful attention to the bladder. After the constitutional disturbance of the early days has passed, massage and passive movements should be given to the paralysed limbs.

In the syphilitic cases a full anti-syphilitic régime should be started as soon as possible (see pp. 223, 1458).

## LOCAL VASCULAR LESIONS OF THE SPINAL CORD

Hæmorrhage into the spinal cord is uncommon apart from pre-existing vascular abnormalities. When it occurs it produces signs of an acute segmental lesion, followed, as a rule, by those of more general hæmatomyelia (see p. 1549).

Local arterial thrombosis is usually due to syphilitic arteritis.

In old people who are the subjects of severe atheroma, transient partial paraplegia occasionally occurs, most of the symptoms passing off within 24 hours or less. The mechanism of its causation is not fully understood.

*There is some reason to think that venous thrombosis in the cord may give rise*

to local lesions involving a greater or less degree of paraplegia, and the residual paraplegia following local extrathecal infective conditions has been attributed to this cause.

Vascular abnormalities resulting from congenital malformation of blood vessels are not very uncommon in the spinal cord. The most usual type is a racemose venous angioma, situated partly within the cord and partly on its posterior surface. These lesions are almost always in the lower half of the cord. Pain of root type affecting the lower limbs and recurring in acute episodes is a salient clinical feature. It may be followed, or even preceded, by wasting and weakness of one or both legs, and sphincter disturbance is usually present during the acute episodes. The reflex findings are often anomalous.

The diagnosis is seldom made until the angioma is exposed at operation.

The superficial vessels should on no account be interfered with, and surgical intervention must be limited to such symptomatic measures as dividing a posterior nerve root for the relief of pain.

### SPINA BIFIDA

The most common developmental abnormality of the spinal cord results from a failure of the neural tube to close perfectly and to separate completely from the surface ectoderm. In consequence of the failure of separation, the mesodermal tissues in which the vertebral arches develop cannot close over the posterior surface of the developing cord at the affected site, and spina bifida ensues. Spina bifida is thus usually associated with some abnormality in the cord itself, and its significance as a clinical finding is that it is a pointer to a local fault of development in the cord.

Spina bifida is not uncommon, and in 90 per cent. of cases affects the lumbosacral region and in about 5 per cent. the lower cervical region. There may or may not be some abnormality of the skin over the affected vertebral arches, or there may be a frank meningocele. Hydrocephalus may be associated. Severe degrees of malformation of the spinal cord are incompatible with life.

**Symptoms.**—Weakness of the lower limbs may be present from birth or from an early age, and may increase, or it may be first complained of about puberty, when the vertebral column elongates and the spinal cord, which in these cases is often adherent at its lower end, becomes pulled upon. The ankle-jerks and possibly also the knee-jerks may be absent, and the muscles of the legs poorly developed and the feet hollow. Congenital talipes may be present. Control over the sphincters of bladder and anus is often imperfect, the former being the more frequently and conspicuously affected. Trophic changes may occur on the feet, and there may be areas of anæsthesia on the feet and on the buttocks. Sometimes the sensory loss is of a dissociated type.

**Diagnosis.**—If the symptoms have been present in some degree since childhood, the diagnosis is usually easy and is confirmed by radiographic examination. When symptoms appear at puberty or later, and there is no external abnormality, spina bifida may not be thought of, but if tumour is suspected radiographic investigation is likely to be undertaken and a bony abnormality is revealed which is in keeping with the clinical findings.

**Prognosis.**—In the less severe cases the symptoms become stationary, and are consistent with a normal duration of life. In the more severe cases which live beyond infancy, the patients become bedridden and succumb at a relatively early age.

**Treatment.**—In most cases, because of the malformation of the cord, no improvement can be expected from operation. Treatment should otherwise be symptomatic, and enuresis should be treated with full doses of belladonna.

## OTHER DISEASES OF THE SPINAL CORD

## SYRINGOMYELIA

**Synonym.**—Status Dysraphicus.

**Definition.**—A chronic disease characterised by the formation in the spinal cord and brain-stem of long cavities with surrounding gliosis. To the disease in the brain-stem the term syringobulbia is often applied.

**Ætiology.**—In most cases the disease begins to cause symptoms during the period of growth, and it is rare for their appearance to be delayed beyond the age of 30. Both sexes may be affected and males are more prone to suffer than females. There is considerable indirect evidence that the disease depends upon a congenital abnormality, and other somatic abnormalities may be present in the same patient. Cavitation in the spinal cord may also occur in association with intramedullary tumours, with spinal vascular disease, with pachymeningitis cervicalis and with hæmangiomas of the spinal cord.

**Pathology.**—At necropsy the cord is enlarged, and cross section reveals a cavity filled with clear or yellowish fluid. It extends up and down for many segments, and the lower cervical and upper thoracic segments are the most frequently and the most severely affected. The cavitation is most marked in the posterior half of the cord and appears to arise at the base of one of the posterior horns, or in the middle line behind the central canal. The cavity does not represent a dilated central canal, for this can often be found separate from it, though the two usually communicate. More than one cavity may be present. It is surrounded by glial tissue which is relatively acellular and often peculiarly translucent. The blood vessels frequently show degenerative changes, and the fluid within the cavity may give evidence of old or recent hæmorrhage. The cavity is so placed that it interrupts the crossing neurones which convey pain and temperature sensations. As it enlarges, the anterior horns of grey matter become involved in its surrounding gliosis and the cells degenerate. Ascending and descending tracts are affected either by pressure as a result of distension of the cavity with fluid, or by the glial process. The posterior columns always survive longest.

In the medulla the disease affects particularly the floor of the fourth ventricle in the region of the hypoglossal nucleus and tends to extend as a slit antero-laterally to a position just anterior to the descending nucleus of the trigeminal nerve. In its course it may destroy the motor nucleus of the vagus and glosso-pharyngeal nerves or emerging fibres of these nerves. The slit interrupts (1) the internal arcuate fibres passing from the cuneate and gracile nuclei to the mesial fillet, and (2) the fibres from the descending nucleus of the vestibular nerve to the posterior longitudinal bundle. The development of this lesion thus (1) renders complete sensory loss which was previously of the typical dissociated type, and (2) causes or increases nystagmus. If the slit reaches far enough it also interrupts some or all of the fibres passing from the descending trigeminal nucleus to the fillet of the opposite side, and so (3) causes dissociated sensory loss on the face on the side of the lesion. The disease may extend up into the pons and, in rare instances, higher.

**Symptoms.**—*Disturbances of sensibility.*—By far the most constant and characteristic feature of syringomyelia is a sensory loss of a peculiar kind which was named by Charcot "the dissociated sensory loss". This is a loss of sensibility to painful impressions and to thermal stimuli, while sensibility to touch, to vibration, to position, to passive movement and to the appreciation of location upon the skin, remain relatively or entirely intact. In other words, those forms of sensibility which travel by a path crossing in the commissures of the spinal cord are lost, because the lesion of syringomyelia destroys especially the region of the commissures, while these

forms of sensibility which travel by paths which are uncrossed in the spinal cord are not affected.

The destruction of the commissures in the lower cervical and upper dorsal regions produces the dissociated sensory loss symmetrically over the thorax and upper extremities, the distribution varying with the extent of the lesion. Only rarely does the symmetrical sensory loss extend below the thorax, for the reason that the spinal lesion does not often extend below the mid-dorsal region. Occasionally the sensory loss varies in depth, extent and symmetry of distribution according to the completeness, extent and symmetry of the lesion. Thus, in early and slight cases, the sensory disturbance may not amount to more than a relative loss of pain and temperature confined to the hands and ulnar borders of the forearms, while in an advanced case there is usually complete inability to appreciate painful and thermal stimuli over an area which would be covered by a sleeved jacket. The area often extends later over the neck and the face. Combinations of the "sleeved jacket" sensory loss with hemianalgesia and hemithermanæsthesia often occur in cases where both the spinal lesion and the medullary lesion are present. The dissociated sensory loss makes its advent insidiously, and is often unnoticed by the patient and discovered for the first time on medical examination. Or it may appeal to the patient, who on bathing finds that he appreciates heat and cold upon some parts of the skin and not on others. Not infrequently he finds that he injures himself or burns himself without noticing it at the time.

Subjective sensibility is not often affected, and for the most part syringomyelia may be described as a painless disease; but there are very notable exceptions. Sensations of heat and cold, dull fixed pains, lasting neuralgic pains, and lightning pains resembling those of tabes, may occur. These pains are confined to the regions which are the seat of the other symptoms.

*Muscular atrophy.*—This is met with in considerably more than half the cases. Though usually bilateral, it is often not symmetrical, and may be entirely confined to one side. The intrinsic muscles of the hands, and the muscles of the ulnar side of the forearms are first and most affected in the ordinary run of cases. The atrophy is often here confined, but it may extend up the arm, though it is unusual for the whole upper limb to be affected. Sometimes the shoulder muscles are first affected, and again the scapulo-thoracic and humero-thoracic muscles may be early involved. The upper intercostals and that section of the muscles which supports the spine supplied from the upper six dorsal segments suffer, but the scalenes seem generally to escape. The muscular atrophy is strictly limited and is apt to become complete in the muscles affected. Fibrillation is not usually present. The lesions of the medulla may involve the motor nuclei of the cranial nerves. Wasting of the tongue on one or both sides is not uncommon, and its discovery in a young subject should always arouse suspicions of the presence of syringomyelia. Unilateral paralysis of the palate, pharynx and all the muscles of the larynx upon the affected side may occur from involvement of the nucleus ambiguus. Similarly, but in much rarer cases, atrophic paralysis of the face, of the trigeminal muscles, of the sternomastoid and trapezius may occur from unilateral involvement of the corresponding motor nuclei. Nystagmus is almost a constant feature.

Contractures resulting from the muscular atrophy are commonly seen in the hands, and the deformity resulting tends towards the "claw-hand" type, but hardly reaches the degree seen in ulnar nerve paralysis, and is often much modified by trophic and vasomotor changes, and by the results of injuries and whitlows.

*Other motor symptoms.*—The lower extremities almost invariably escape so far as atrophy of muscles is concerned but usually present a slight spasticity, with the signs of involvement of the crossed pyramidal tracts. This does not often produce much disability. In cases, however, where the lesions involve the lateral region of the cord, either by direct extension or by the pressure of distended cavities, severe spastic

paraplegia may result. And again, in very rare cases, such pressure may lead to total avascularisation and total transverse lesion of the spinal cord with the appearance of a complete flaccid paraplegia with incontinence, total sensory loss and absent deep reflexes.

Sphincter trouble is usually absent, or slight and occasional; but in cases in which paraplegia is severe any degree may occur.

The skin reflexes of the trunk are diminished or absent and the plantar reflexes are of the extensor type, according to the degree of pyramidal involvement. Some degree of pes cavus is often present. The knee-jerks and ankle-jerks are increased, while the arm-jerks, even in the absence of muscular wasting, are characteristically absent.

Spinal curvature is present in many cases. It consists essentially in a kyphosis or kypho-scoliosis of the upper dorsal region, with a compensating lordosis and lateral curve in the lumbar region. The upper convexity is to the left, because of the major use of the right hand. It is dependent upon paralysis of the trunk muscles, from involvement of the anterior horns in the upper dorsal region, and, in addition, dystrophic changes in the bones may be factors in its production. It is more marked the earlier it commences during the period of growth, and in cases in which heavy manual occupation has been followed.

*Trophic and vasomotor disturbances.*—Thickening of the bones or a condition of osteoporosis and brittleness may be met with. More often Charcot's arthropathy occurs. It differs in no way from the similar condition in tabes dorsalis, but being confined to the joints of the analgesic region it affects those of the upper extremity. The most characteristic of the trophic changes consists in thickening of the subcutaneous tissue and of the skin itself, which is seen in the hands. The fingers become thick and swollen, and lose their natural outline, the tips become blunted and the knuckle-folds thick and coarse, and vasomotor disturbance renders them unduly red, or even blue. They have been termed "sausage-like" fingers, and often stand out in contrast to the wasting of the intrinsic muscles of the hand. A similar condition affecting the whole hand is common, and was termed by Charcot the "fleshy hand" or "main succulente". The analgesic condition of the hands and the thermanæsthesia present expose them unduly to injuries and, since the injuries are likely to be unnoticed or disregarded, septic infection arises easily, and the results of injuries, burns and whitlows are frequently seen, giving rise to further deformity from scars, or loss of the terminal phalanges.

Considering that the efferent neurones of the cervical sympathetic system have their origin in the brain-stem, and their exit from the spinal cord in the upper dorsal segments, thus traversing the whole of the region usually affected by the lesion of syringomyelia, the frequency with which *paralysis of the cervical sympathetic* occurs is easily understood. It may be complete or incomplete, unilateral or bilateral, and is recognised by smallness of the pupil, narrowing of the palpebral aperture (sympathetic ptosis) and a peculiar flatness of expression on the side of the face affected, with decrease or loss of sweating. These signs are much more obvious when unilateral than when bilateral, for, in the absence of the contrast which a normal side of the face gives, they are often overlooked when bilateral.

*Morvan's disease.*—This is a condition of great rarity, in which a chronic peripheral neuritis is combined with syringomyelia, with consequent very severe effects upon the extremities. There is absolute loss of all forms of sensibility in the hands and in some cases also in the feet, together with atrophy of the intrinsic muscles. The cause of this complication of syringomyelia is unknown.

*Diagnosis.*—Syringomyelia has to be differentiated, in its early stages, from those diseases which cause slowly progressive muscular atrophy in the upper extremities, and, in its later stages, from other lesions of the central region of the spinal cord. Those cases in which the lesions are chiefly in the ponto-medullary region must be distinguished from other slowly oncoming lesions of the brain-stem.

The age of onset, during the later years of childhood and the earlier years of adult life, is important, and during this period slowly developing paralysis with sensory loss, and with or without muscular atrophy should always suggest the possibility of syringomyelia. Other causes, which may produce this system group, and which may be confused with syringomyelia, are local lesions of the brachial plexus, and, especially, the lesion produced by the presence of cervical ribs, root lesions, lesions of the central grey matter of the spinal cord, especially central tumours of the spinal cord, and hæmatomyelia. That the peculiar sensory changes of syringomyelia are usually the first signs of that disease is important; but this rule has many exceptions, both as to the nature of the sensory changes and as to their time of appearance. When sensory changes are not an early sign the diagnosis has to be made from such diseases as progressive muscular atrophy, peroneal atrophy and myotonia atrophica.

Local lesions of the peripheral nerves produce signs which are confined to the distribution of the nerve involved; the sensory loss is to all forms of sensibility, and the condition is ordinarily unilateral. While these features are sufficient to distinguish such lesions from syringomyelia in nearly all cases, nevertheless in certain rare instances of syringomyelia the sensory loss and the muscular atrophy may be so narrowly confined to the distribution of the ulnar nerve as to cause close resemblance between the two conditions. Any sensory loss over the trunk, or signs outside the distribution of the peripheral nerve, will, if present, clearly divide the two conditions.

Cervical ribs may produce slowly progressive atrophy of muscles, pains and sensory loss, very difficult to distinguish from those resulting from syringomyelia. The diagnosis in these cases is beset with peculiar difficulties, for so frequently do cervical ribs produce no nervous symptoms at all that their presence, when demonstrated, does not argue that they are the cause of the symptoms. Again, cervical ribs are among the commonest of the developmental peculiarities which are so frequently seen in the subjects of syringomyelia. Slow muscular atrophy and slowly oncoming sensory loss and perhaps pain characterise both syringomyelia and cervical rib paralysis, and the distribution may be unilateral or bilateral in either condition; but it is only when the manifestations are strictly confined to the upper extremities and neck that difficulty arises. The slightest physical sign outside of this region at once turns the diagnosis in favour of syringomyelia, and of these signs cervical sympathetic paralysis, sensory loss on the trunk and alteration of the abdominal and plantar reflexes are the most important. A very careful search must be made for any such signs, and the patient observed over a considerable time before a certain diagnosis is made.

Lesions of the central grey matter of the spinal cord may produce a symptom-complex, closely resembling that of syringomyelia. Central tumours of the spinal cord, when of slow growth, are hardly distinguishable, inasmuch as the lesion of syringomyelia is in reality a central tumour of the cord. The majority of central tumours, however, are of more rapid development, and speedily produce severe paraplegia.

Progressive muscular atrophy in its early stages may cause difficulty in diagnosis, since the muscular atrophy in syringomyelia may occasionally precede the appearance of any sensory loss or may be well marked when the sensory loss is slight. In this connection, widely distributed fibrillation is of great importance in indicating a diagnosis of progressive muscular atrophy, particularly if it be seen in muscles not conspicuously wasted. In peroneal atrophy the atrophy of the intrinsic hand muscles is always preceded by a more extensive atrophy of the muscles below the knee, which are rarely atrophied in syringomyelia.

Syringomyelia of the brain-stem (syringobulbia) may be distinguished from other lesions of this region by its insidious onset and the special tendency to the involvement of the lateral region of the medulla, so giving rise to a unilateral paralysis of palate, pharynx and larynx with hemianalgesia and hemithermanæsthesia on part

of the face and even on the opposite half of the body. Often some signs of cervical syringomyelia coexist; but the medullary lesion may exist alone, and it cannot be too prominently borne in mind that any very slowly progressive lesion of the brain-stem of insidious onset may be of the nature of syringomyelia.

**Course and Duration.**—The malady, commencing insidiously, progresses very slowly, and often ceases to progress for periods which may amount to many years. The tendency to the destruction of life is not great; but when rapid extension of the physical signs, and especially of paralysis and muscular atrophy of the upper extremities and respiratory muscles, occurs, the end is likely to come quickly. Signs of great distension of the cavities, such as pain and rigidity of the neck, and also severe and increasing paraplegia, with sensory loss of all forms of sensibility below the level of the lesion, point to a rapidly fatal termination. In rare instances acute exacerbations of the manifestations occur, and are followed by partial remissions. Such episodes are due to hæmorrhage into the syringomyelic cavity, and when death has occurred in the course of one of them, the cavity has been found filled with blood.

It is not unusual to meet with well-marked cases in which the signs develop and increase during late childhood and early adult life, and then remain more or less in a stationary condition, allowing an occupation to be followed until well after middle life has been reached; but with the advent of the degenerative period of life, from 45 years onwards, there is often a slow increase of the disability which puts an end to useful capacity. The patients succumb to intercurrent disease, and few reach the age of 60 years.

**Prognosis.**—Recovery never occurs; but arrest of the disease for long periods is frequent. Those disabilities, which are the result of pressure or distension, may abate spontaneously or as the result of treatment, and in arrested cases training may bring about lessening of the disability. Increasing symptoms, especially if the increase be rapid, are always a cause for anxiety, and increasing involvement of the respiratory muscles is the gravest of events.

**Treatment.**—In the vast majority of cases nothing can be done to retard the slow but relentless progress of the disease and treatment is therefore symptomatic. Radiotherapy has been used and occasionally diminishes the spontaneous pains. Rarely the presence of a dilated cystic cord may justify surgical operation and evacuation of the cyst.

## HÆMATOMYELIA

**Synonym.**—Spontaneous Hæmatomyelia.

**Ætiology and Pathology.**—Hæmatomyelia, or hæmorrhage into the spinal cord sufficient to cause symptoms is a rare disease. It appears to arise almost exclusively when there is some abnormality of the spinal vessels, and in particular some variety of angioma; excessively rarely it is associated with syphilitic disease of the spinal arteries, and equally rarely with hæmophilia. Hæmorrhage may occur into a syringomyelic cavity. The hæmorrhage is nearly always centrally situated, and shows a strong tendency to spread longitudinally and may extend over many segments.

Males are affected far more often than females, and the main incidence is in the first half of adult life.

The clinical effects resulting from trauma of the cervical cord have in the past often been attributed to hæmatomyelia, and may be due to this cause, but it is now known that in the majority of such cases no significant hæmatomyelia is present.

**Symptoms.**—Prodromal symptoms may occur in the form of local weakness or transitory sensory disturbances. In most cases the actual onset is sudden, and the symptoms attain a considerable severity in the course of a few minutes, but they may continue to increase for an hour or two.

The symptoms vary according to the site and the extent of the extravasation. In the majority of cases at first there is paraplegia, with more or less complete motor and sensory paralysis up to the level of the lesion, and usually with pain at the upper limit of the disturbance. As the hæmorrhage extends longitudinally these manifestations are quickly followed by a syringomyelic type of sensory loss.

Sometimes, but not usually, blood is found in the cerebrospinal fluid. **Diagnosis.**—The diagnosis of primary hæmatomyelia rests upon the sudden onset, the rapid development of symptoms, which soon come to a standstill, and the physical signs of a central lesion of the spinal cord. The distinction has to be made from acute myelitis. Acute myelitis, though rapid in onset, rarely shows the sudden development of symptoms seen in hæmatomyelia, and the sensory loss which accompanies it is not of the syringomyelic type. Prodromata often precede the onset in both conditions.

**Prognosis.**—Hæmorrhage in the cervical region may be rapidly fatal from respiratory paralysis. In the non-fatal cases a variable degree of recovery occurs, and in many a syringomyelic type of dissociated sensory impairment ensues, the intensity of the loss being usually less than in syringomyelia.

**Treatment.**—The general treatment is that of any severe spinal cord lesion with paraplegia. Absolute rest is essential. When there is evidence that a syphilitic lesion of the spinal arteries is in question, the treatment is that of spinal syphilis. Angioma and other malformations of the spinal vessels are not amenable to surgical intervention.

## SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

**Definition.**—A progressive disease associated with pernicious anæmia, in which the white matter of the spinal cord degenerates, the incidence of the lesions being particularly on the posterior and the lateral columns.

**Ætiology.**—It has now been determined that when subacute combined degeneration occurs pernicious anæmia is always present in some degree, but the degree of anæmia is extremely variable. The spinal affection is evidently not the result of the anæmia, but the spinal disease and the blood disease are both due to the absence of an essential factor now identified as cyanocobalamin (Vitamin B<sub>12</sub>); both are associated with complete gastric achylia.

As in the case of pernicious anæmia, familial incidence has been recorded. First met with in the third decade of life, the malady in former times became increasingly frequent until a maximum incidence occurring in the sixth decade, while cases commencing in the seventh decade were not uncommon. Owing to the earlier recognition and adequate treatment of pernicious anæmia the condition is becoming increasingly rare in this country.

The cases seen are often atypical and may occur in patients with Addisonian anæmia in whom the treatment has been inadequate. The sexes are equally affected.

**Pathology.**—The pathological and clinical features of the disease were established in a classical paper by Russell, Batten and Collier published in 1900. The essential lesion is degeneration of the myelin sheaths and subsequent degeneration of the axis cylinders in the posterior and lateral columns. Similar degenerative changes are found in the peripheral nerves. The myelin swells and later disintegrates. This change first occurs in the lower dorsal region of the cord, and is first seen in the centre of both posterior columns, and soon afterwards in the centre of either lateral column, as small areas of a darker and more translucent appearance than the normal white matter. It is only at an early stage of the disease that the anatomical picture is strictly one of posterior and lateral degenerations, for soon after, spots of degeneration appear on either side of the anterior median fissure and in other parts of the antero-lateral columns. The degenerated areas increase in size centrifugally,

coalesce with one another, reach the surface of the cord and eventually involve the whole of the white matter of the cord as seen in transverse section, with the exception of the narrow zone of short internuncial fibres which everywhere clothe the grey matter. Occasionally the disease is confined to the posterior columns.

From its starting-point in the lower dorsal region the degeneration spreads upwards and downwards in the white columns of the spinal cord, by means of the occurrence of small isolated spots of degeneration in the posterior, lateral and anterolateral columns, which increase in size and thus join the area previously degenerated. The degeneration tends to extend upwards indefinitely, and in severe and advanced cases has been found in the pyramidal tract as high as the internal capsule.

The lesions of the white columns entail the usual secondary degeneration, both ascending and descending; but these occur late, and are often much less obvious than might be expected from the severity of the local lesions. The destruction of the axons by the local lesions also causes a series of retrograde changes in the corresponding nerve-cells, and tigrolysis, vacuolation, shrinking and neurophagy may be conspicuous, especially in the cells of Clarke's column and in the cells of Betz, which give origin to the pyramidal fibres. There is never any inflammatory exudate, and a peculiar feature is the absence in untreated cases of any glial proliferation.

When degeneration in the peripheral nerves is severe the muscles are conspicuously wasted in the later stages, and the muscle fibres show great diminution in size and poor striation. There is not any considerable increase of the muscle nuclei, and little or no fibrosis is found.

*The blood.*—Usually the blood shows a hyperchromic anemia of varying severity; the hæmoglobin ranges from 35 to 75 per cent., the lower of these figures being common; the colour index is above the normal and may be as high as 1.6. Macrocytosis is present. Anisocytosis, poikilocytosis and polychromasia are common. Normoblasts are often numerous and megaloblasts may be found in numbers. In a few instances, anemia has been absent throughout, the hæmoglobin content and the cytology being normal; this has occurred chiefly in cases which have run an acute and fatal course in a few months. Sternal puncture shows a megaloblastic marrow. A relative lymphocytosis is almost always present, and may reach as much as 55 per cent. *This change occurs early and is helpful in the confirmation of the diagnosis of the nervous disease.* Achlorhydria is always present in the stomach, even after the administration of histamine.

A careful investigation of the blood-changes at various stages of the disease and of the post-mortem findings in a large series of cases has proved beyond any possible doubt that the blood-changes in subacute combined degeneration are identical with those met with in the various stages of pernicious anemia. The cerebrospinal fluid is normal.

*Symptoms.*—(1) *Nervous.*—In a large majority of instances the symptoms appear insidiously and without any recognised exciting cause. Sometimes the onset is more rapid and may be preceded by gastro-intestinal symptoms, or the patient may go to bed for a few days with an attack of "influenza" and on getting up again may be grossly unsteady.

The first nervous symptom is usually numbness or tingling in the feet, and if the patient is asked he will usually admit that he has a slight sensation of the same kind in the fingers. Less often the sensation in the feet is one of swelling, or coldness, or as if walking on cotton wool; and in a few cases unsteadiness in walking is at first the only complaint. Very soon weakness in the legs is experienced, and the numbness gradually spreads farther up, and the patient begins to feel unsteady in walking.

Examination at this time reveals a slight degree of weakness in movement of the toes or in dorsiflexion of the feet, diminution or absence of the ankle-jerk, probably an extensor plantar reflex, and a variable degree of sensory loss; the latter is usually

most marked for vibration and for sense of position in the toes and then for light touch. There may be some tenderness of the feet or calves. Romberg's sign is positive. The superficial sensory loss is at first only over the feet, then it spreads up to cover a "sock" area, and later has a "stocking" distribution, pain and temperature impairment meanwhile being added to it. Loss of deep sensation however generally predominates, and unsteadiness may be very pronounced at a time when other signs are slight or absent. At the stage we are referring to there are usually no objective disturbances in the upper limbs, although intense numbness in the hands may be complained of.

If the condition is allowed to progress, either the signs of peripheral nerve disease or those of spinal cord disease may predominate. In the former case the knee-jerks become diminished and the ankle-jerks lost, the muscles below the knees become paralysed and flaccid and eventually waste, deep sensory loss is severe, and there is loss of all forms of superficial sensation over a "stocking" area. The paralysed muscles become very tender, flexion spasms may set in and every movement is agonising. In the upper limbs a variable degree of sensory loss may develop with astereognosis in the hands and loss of superficial sensation over a "glove" area. The supinator-jerks may be abolished, but rarely the biceps and triceps jerks. If the signs of spinal cord disease predominate, the legs tend to become spastic, the reflexes are strongly extensor. Sensory loss is less marked as a rule than when the signs of peripheral disease predominate, but deep sensation is always greatly impaired, and as time goes on there is considerable loss of pain and temperature appreciation, extending over the lower limbs and to a gradually higher level on the trunk. In the arms the tendon jerks may be increased. Except in advanced cases sphincter disturbances are slight.

The cranial nerve functions are usually unaffected, but optic atrophy is an important complication which occurs in a small percentage of cases, and the visual disturbances due to it may be the first symptom. Slight nystagmus is common.

Mental changes occur in a small proportion of cases, at a time when the degree of anaemia is not sufficient to account for them. Apathy, mild dementia and confusional psychosis with impaired memory and disorientation are the commonest types of disturbance.

(2) *Anaemia*.—Although anaemia is one of the most characteristic features of subacute combined degeneration, since it is found in every case of long duration at some time or other and, moreover, it is sufficiently striking as at once to suggest the diagnosis in at least two-thirds of all the patients when they first come under observation for nervous symptoms, yet it may be absent throughout the course of the disease in a rapid case, and its appearance may be delayed until several years after the disease of the nervous system is manifest. The anaemia in almost every case is identical in every respect with pernicious anaemia. Of those cases in which the blood picture is not typical, nearly all show megalocytosis, with a relative lymphocytosis and a high colour index, as do early cases of pernicious anaemia, and it may be said with certainty that the longer the patient survives, the greater the likelihood of typical pernicious anaemia developing. The spleen has been found to be enlarged in many cases, and the marrow of the bones is typical of pernicious anaemia, as may be also the iron reaction in the liver and the changes in the myocardium and other muscles. As in pernicious anaemia, the tongue is clean and glazed, and this occurs so regularly that any appearance of furring of the tongue may justly be said to exclude the diagnosis of this disease; a history of soreness of the tongue is obtained, if enquired for, in more than half the cases. Fractional test meals show an absolute achlorhydria as in pernicious anaemia. The colour of the skin is often peculiar and striking, even when anaemia is not severe, and is best described as "biscuit coloured". A bright malar flush upon this yellowish biscuit-coloured background gives a characteristic

and vivid facial aspect in the earlier stages of many of the cases. The manifestations common to all anæmic states, breathlessness, headache, cardiac and venous murmurs and œdema, are commonly present, but hæmorrhages are infrequent. Syncopal attacks may occur. Attacks of diarrhœa are common, but, on the other hand, constipation may be obstinate. Irregular pyrexia is almost invariably present at some period in the course of the disease, and this quite apart from fever-producing complications, such as cystitis and bed-sores. In the later stages progressive emaciation is constant, and if life be prolonged it becomes extreme.

**Diagnosis.**—In the early stages of the disease, when peripheral paræsthesiæ dominate the picture, the condition has to be distinguished from peripheral neuritis and occasionally from peripheral arterial disease. In the well-developed stages of the disease, its recognition presents no great difficulty. Attention is quickly attracted by the conspicuous anæmia and biscuit-coloured skin. Following a period of slight paraplegia, the steadily increasing paralysis of the lower extremities, producing complete and lasting helplessness, the characteristic distribution of the sensory loss, the irregular pyrexia, the anæmia and the relatively late onset of sphincter trouble serve to separate this disease from other forms of paraplegia. The change from the spastic to the flaccid type of paraplegia with loss of the deep reflexes and persistence of the extensor response, which occurs in some of the cases in the late stages, is highly characteristic.

In the earliest stages and before the appearance of any definite evidence of organic spinal disease, there may be such disability as to suggest hysterical paraplegia or ataxia, and only the examination of the blood may expose the real disease. When there is evidence of organic spinal disease, it is especially from disseminated sclerosis, spinal tumour, tabes dorsalis and polyneuritis that the diagnosis has to be made. The preponderance of peripheral subjective sensations and the anæmic appearance should always suggest a diagnosis of subacute combined degeneration. Slight spastic ataxia is the common clinical picture of subacute combined degeneration, of disseminated sclerosis and of spinal tumour. The presence of objective peripheral sensory loss is in favour of subacute combined degeneration, whereas diplopia, nystagmus, transient amblyopia and intention tremor are strongly in favour of disseminated sclerosis. Spinal tumour is especially distinguished by a sharp line of sensory loss, transverse to the axis of the body, which does not spread up from below in slow fashion.

When subacute combined degeneration commences with flaccid ataxia and loss of deep reflexes, the distinction must be made from tabes dorsalis. The extensor plantar reflex, which is almost always present in the former disease and which is rare in early tabes, the different distribution of the sensory loss in the two diseases, the loss of power and associated anæmia in subacute combined degeneration, and the results of the examination of the blood and cerebrospinal fluid for syphilitic reactions and of the latter fluid for lymphocytosis, are important aids in the differential diagnosis.

It is also necessary to bear in mind the strikingly close resemblance the disease we are considering may bear to polyneuritis. The differentiation may in the early stages depend chiefly, if not wholly, upon the examination of the blood and the result of a fractional test meal. But, sooner or later, the appearance of an extensor response will indicate the presence of a cord lesion. On the other hand, in the spastic type, the presence of muscular tenderness in the legs is a strong indication in favour of subacute combined degeneration.

**Course and Prognosis.**—Before the days of effective treatment the duration of the disease varied within wide limits. In some the progress was rapidly downhill, survival being a matter of months from the first recognition of the symptoms; in others the disease remained for several years in a relatively mild stage, and partial remissions were common, but once the patient became bedridden the survival period was usually short.

With the advent of liver therapy for pernicious anæmia the outlook for subacute combined degeneration was not at first greatly changed, but with more potent liver preparations and the development of an adequate technique of treatment, improvement and, later, cure soon became apparent. For the case that comes under intensive treatment before the patient has become quite unable to walk, functional cure usually takes about 6 months to a year. Some reflex abnormalities, which mean nothing to the patient, may still persist for a time or permanently. Some authorities believe that cases of the flaccid type, in which the element of peripheral neuritis predominates, respond better to treatment than do those that are more spastic, the disease in the latter being chiefly in the spinal cord. No such generalisation can however be made, and in cases of the latter type the extensor plantar reflex, usually the most persistent sign of spasticity, may disappear. Advanced cases of both types may fail to show much response to treatment. But no case, however advanced when first recognised, should be deprived of full treatment on this ground, and the most surprising recoveries are sometimes seen. If treatment is stopped relapse occurs sooner or later, and with renewed treatment recovery again ensues, but it is doubtful whether this process can be frequently repeated, on account of the probability of gliosis in the spinal cord.

**Treatment.**—Whatever the degree of anæmia present, intensive replacement treatment is essential. Cyanocobalamin (Vitamin B<sub>12</sub>) has now, for practical purposes, superseded the various forms of liver concentrates. For the first month this should be given in doses of 100 microgrammes on alternate days. Thereafter the dosage may be very gradually reduced provided that the blood picture is satisfactory and the ultimate maintenance dose may be as little as 100 microgrammes monthly. The blood-count should be brought up as quickly as possible to five and a half million red cells per cubic millimetre, and kept at that level. The more advanced the stage of the disease the more prolonged will need to be the period of intensive treatment and the more severe the residual disability is likely to be.

Any suppurative condition of the body should be energetically treated. Every care should be taken to prevent bed-sores and cystitis. When present these are often amenable to treatment in the early stages of the disease and also in less acute cases, but in the later stages and in the more acute cases they are inevitable and the bodily vitality is too low for any reparative process to take place. Pains are relieved by such analgesics as aspirin, acetanilide, amidopyrine and phenazone. Flexor spasms are among the most troublesome of the symptoms, since their frequent occurrence denies sleep to the patient and they are most important factors in the occurrence of bed-sores. The remedy which seems to have most effect in checking these spasms is barbitone.

## PROGRESSIVE MUSCULAR ATROPHY

**Synonyms.**—Motor Neurone Disease; Amyotrophic Lateral Sclerosis.

**Definition.**—It is usual to describe together a large group of cases in which progressive wasting of the musculature of the body and a moderate degree of spasticity are associated with, and evidently secondary to, widespread degenerative changes in the central nervous system, the chief incidence of which is on the lower and upper motor neurones. Clinically the cases are capable of great variety, according to the sites of the initial wasting and the degree of spasticity, but they are nearly all comprised by three clinical types. In the first and most common type, the wasting begins in the upper limbs, and the lower limbs become spastic but do not waste. This variety was called by Charcot *amyotrophic lateral sclerosis*. In the second type, the wasting commences in the muscles innervated from the medulla and pons, and the names *progressive bulbar paralysis* and *labio-glosso-pharyngeal paralysis* are applied to it. In the third type, the wasting begins in or quickly spreads to the lower limbs and no

spasticity develops: this is called the *purely atrophic type*. Transitions between these types may be met with, and the first two are frequently combined.

**Ætiology.**—The disease is rare before the age of 25, but occurs at all ages thereafter, attaining its maximum incidence between 30 and 45. Males are affected much more frequently than females. No causal factors have been discovered. The pathological findings are most in accord with the suggestion that the malady is due to a deficiency of some element essential to the nutrition of the spinal cord, in the same sense that subacute combined degeneration and pellagra are the results of such deficiencies. The question of the relation of trauma to the causation of progressive muscular atrophy admits of no decisive answer. In occasional instances the onset follows more or less closely on an injury, but we know of no pathological process whereby a peripheral injury can set up a diffuse degenerative process within the central nervous system. Injury of the cervical portion of the spinal cord may produce a syndrome embracing wasting in the upper limbs and spasticity in the lower limbs (see p. 1541), thus superficially resembling amyotrophic lateral sclerosis, but there is not sufficient evidence that trauma can cause the progressive and ultimately fatal malady of which true amyotrophic lateral sclerosis is the most common clinical variety (see Diagnosis, p. 1560).

In rare instances progressive muscular atrophy has been described in the subjects of old acute anterior poliomyelitis. Certain cases of syphilitic amyotrophy (see p. 1470) present clinically a close resemblance to amyotrophic lateral sclerosis.

**Pathology.**—While in the less advanced cases the degenerative changes are almost limited to the anterior horn cells and the pyramidal tracts, in the most advanced they affect almost all the structures of the cord with two striking exceptions, namely, the fibres of the posterior columns, and the fine fibres passing forward in the grey matter. It will be noted that the former fibres and probably the latter also have their cell bodies outside the central nervous system. The latter probably subserve reflexes; their preservation seems to be constant in amyotrophic lateral sclerosis and not in other forms of progressive muscular atrophy, and it is probably to be correlated with the preservation of the tendon reflexes in the wasting muscles which is a peculiar and striking clinical feature of amyotrophic lateral sclerosis.

To the naked eye, a cross-section of the spinal cord may show some diminution in size of the ventral horns. The essential lesion is a primary degeneration of the cells in the ventral horns of the spinal cord and in the homologous motor nuclei of the brain-stem, namely, the hypoglossal, facial, trigeminal and oculo-motor nuclei. Coupled with the degeneration of the lower motor neurones is a degeneration of the upper motor neurones of the pyramidal system. In the ventral horn cells the degeneration is evidenced by a gradual shrinking in size of the cells, which lose their dendrites and become oval or spherical in shape. The Nissl bodies slowly disappear, and only in rare and rapid cases is definite chromatolysis seen. The nuclei dwindle and become irregular and distorted.

The dorsal and lateral horns are almost invariably intact, but degenerative changes are sometimes seen in the cells of Clarke's column. The affection of the motor nuclei of the brain-stem in the bulbar cases is in every way similar to that of the ventral horns. The degeneration of the motor nerves which take origin from the degenerate ventral horn cells, often proceeds *pari passu* with the degeneration of the cells, but in some cases this is conspicuously not so.

The affected muscles are soft and toneless, and the muscle fibres are found irregularly degenerated, bundles of normal and of degenerating fibres being found side by side until the atrophy is complete. The characteristic change is shrinkage of the affected fibre to a calibre much less than normal. As is usual in all slow tissue degenerations, fibrosis and local arterial disease accompany the atrophy of the muscle fibres.

The pyramidal neurones (cells of Betz), which characterise the precentral cortex, undergo a degeneration very similar to that of the ventral horn cells, but with this

difference, that the earliest structural changes are found in the most distal part of the pyramidal fibres. The degeneration of the upper motor neurones never proceeds to the complete destruction of anything like all the pyramidal fibres. Degenerative changes are constantly present also in the anterior columns of the spinal cord.

The pathological picture, therefore, of progressive muscular atrophy is a widely scattered degeneration of nervous elements, not confined to the motor systems, though these are predominantly affected.

**Symptoms.**—The onset is in most cases very gradual, but it may be more rapid, and severe incapacity may result in the course of a few months. In rarer cases, a severe degree of paralysis may develop in the course of a few days, and in such cases it is not uncommon to see the most remarkable temporary improvement. The nature of the onset, as a rule, indicates the course which the malady will pursue. A very slow onset is followed by a very slowly advancing disease, often interrupted by long stationary periods, whereas the more rapid the commencement, the quicker will be the advance and the sooner will a fatal issue occur. Accompanying and sometimes preceding the onset, and not infrequently conspicuous during the early states of the disease, are certain sensory symptoms which, from the confusion in diagnosis they may cause and from the scant attention which has been paid them in descriptions of the malady hitherto, deserve emphasis. These symptoms are confined to the regions where the wasting first appears, and consist in a subjective feeling of stiffness and uselessness, much increased when the limb or the body is cold. Or there may be dull aching pains, intermittent neuralgic pains which may be severe, or a sensation of coldness or numbness which may be intense. Painful cramp in the muscles which are about to be affected is comparatively common. The attention of the patient may be first drawn to his malady by the altered appearance produced by the atrophy, and this is more common when the commencement is in the hands, where the subcutaneous tissue is thin and the region constantly in view. More often the disability consequent upon the weakness is noticed first; this is always the case where the commencement is in the bulbar muscles, and usually also where the muscles of the legs, proximal muscles of the arms and trunk muscles are first involved. Lastly, the fibrillation may be so marked as first to attract notice.

The *muscular wasting*, which constitutes the most characteristic feature of the disease, may commence in any group of the skeletal muscles whatsoever. It may be first manifest in such rare situations as the facial muscles, intercostal muscles, muscles of the back and abdominal muscles. The commonest situation is in the muscles of the upper limb, where the distal (intrinsic muscles of the hand) or the proximal muscles (deltoids, spinati, etc.) are first affected in about an equal number of cases. In the hand, the muscles of the thenar eminence are the first to waste, and this is followed by atrophy of the hypothenars, of the lumbricals and of the interossei with the usual flattening of the palm, exposure of the flexor tendons in the palm from loss of the bulk of the lumbricals, hollowing of the interosseal spaces and a tendency to the "claw" attitude of the hand. This *main en griffe* is never so marked in this disease as in paralysis of the ulnar nerve, syringomyelia, etc., because the wasting soon affects the long flexors of the fingers, and, moreover, contractures of the affected muscles are not marked in progressive muscular atrophy. When the upper arm is primarily affected the wasting is usually first seen in the deltoids, whence it spreads upwards, involving the spinati and the muscles attaching arm to scapula, and arm and scapula to trunk. Among these muscles some tend to escape the atrophy relatively, or to be affected much later than others, and these are the triceps, the latissimus dorsi, the lower half of the pectoralis major, the levator anguli scapulae and especially the upper half of the trapezius, which for this reason was called "*ultimum moriens*" by Duchenne. In the limbs the wasting always commences in one limb, but soon spreads to the corresponding limb of the opposite side and tends ultimately to become symmetrical.

The type of muscular wasting which is characteristic of amyotrophic lateral sclerosis and present less often in other forms of progressive muscular atrophy is that which was called by Gowers "*tonic atrophy*". It might be expected that when degeneration began in a group of anterior horn cells, the corresponding muscles would gradually lose their tendon reflexes and become inexcitable. But in amyotrophic lateral sclerosis, while the muscles waste, their tendon-jerks become and remain exaggerated, and the wasting muscles, though they hang flabbily on the limbs, become hyperexcitable to percussion and they show spontaneous contractions of groups of fibres, known as fibrillary twitchings or *fibrillation* or fasciculation (see p. 1559).

In other forms of progressive muscular atrophy, the wasting muscles are more liable to lose their tendon-jerks, they may be inexcitable to percussion of the muscle bellies, and they show less, if any, fibrillation.

Accompanying the muscular wasting there is usually considerable wasting of the subcutaneous tissues and the skin becomes very loose, and the reduced and separated muscles stand out when they are voluntarily contracted. In some cases the subcutaneous tissue does not waste and may even be increased (especially in the lower limbs), and then the muscular wasting may be masked for a long time even till paralysis becomes complete. There may be an appearance of vasomotor paralysis—redness, blueness and some swelling of the periphery—but this seems to occur much more as the result of the continual pendent position of the hands and of the absence of muscular activity which normally aids the circulation than as the result of any definite vasomotor palsy.

While, in the most usual type of case, muscular wasting is going on in the upper limbs, slight signs of spasticity gradually develop in the lower limbs. The knee-jerks and ankle-jerks become exaggerated, and after a time the plantar reflexes become "*extensor*". There is not often a severe degree of spasticity and sometimes palpable spasticity is absent, although the reflex signs of pyramidal disease are present. The parts which become spastic do not, in general, develop any wasting.

Spasticity from the upper motor neurone disease may develop in the lower extremities before there are any signs elsewhere of atrophic paralysis due to the lower motor neurone lesion, and such cases present the physical signs of a primary lateral sclerosis. It must, therefore, be borne in mind that a case presenting such features in an adult may eventually prove to be one of amyotrophic lateral sclerosis.

In some cases of progressive muscular atrophy no abnormal clinical signs are found in the lower limbs, but, post mortem, degeneration of the pyramidal tracts is evident.

Next in order of frequency to initial wasting in the upper extremities comes the incidence of the disease upon the muscles concerned in facial expression, articulation, mastication and deglutition, and in lesser degree upon the muscles of phonation. The disease may be confined to these muscles throughout the whole of its course. From the widely different clinical picture resulting, and from the fact that all these muscles are supplied from the brain-stem and upper two segments of the spinal cord, this form of the disease has borne the name of *progressive bulbar paralysis*, or *labio-glosso-pharyngeal paralysis*. The wasting commences in the intrinsic muscles of the tongue and spreads thence to the orbicularis oris, to the extrinsic muscles of the tongue, pharynx and larynx, to the muscles of mastication and, eventually, but in less degree, to the facial muscles generally; but only in rare cases are the oculo-motor muscles affected.

The intrinsic muscles of the palate, the constrictors of the pharynx, the intrinsic muscles of the larynx and the muscle of the œsophagus are little affected. This seems at first an anomalous and astonishing fact, considering how great and important are the troubles with deglutition in bulbar paralysis. But the anomaly disappears at once when one considers that the muscles which are concerned with buccal deglutition are

the muscles of the tongue, those forming the floor of the mouth, including the mylohyoid and the digastric, the muscles which raise and lower the jaw, and those of the lips. Further, the muscles which are most important in pharyngeal deglutition are those which raise and lower the hyoid bone and larynx as a whole, and these are the stylohyoid and stylopharyngeus, the palatoglossus and palatopharyngeus, the geniohyoid, thyrohyoid, sternohyoid, sternothyroid and omohyoid. All these muscles are early and severely affected in bulbar paralysis; and when they fail, the intrinsic muscles of the palate are unable to shut off the naso-pharynx, the constrictors of the pharynx are entirely unable to perform the act of deglutition, and the intrinsic muscles of the larynx—though phonation is never lost—are unable, since the larynx is unfixed by the extrinsic muscles, to modulate the tone of the voice. The very active pharyngeal reflex and the difficulty in using the laryngoscope on account of spasm of the pharynx in the subjects of this disease, are very good clinical evidence that the pharyngeal constrictors are not affected.

The earliest physical sign of bulbar paralysis is the loss of the finer movements which are essential for correct articulation, and consequently a slurring dysarthria develops and increases, and the consonants become less and less distinct until they are inaudible. The failure of the palate to close upon the posterior pharyngeal wall begets a nasal element in the voice. Later, the patient becomes unable to interrupt his blast at any of the stop positions, and his utterance becomes a long, moaning, monotonous, inarticulate sound. His phonation remains, but he cannot alter its pitch nor divide it into parts of speech, except by taking a fresh breath. The orbicularis oris is early affected, and the lips lose their firmness and become thin, and as they weaken, the unopposed retractors of the angles produce a wide, straight mouth, both at rest and in emotional action. Whistling and pursing up the lips become impossible, and ultimately there is much dribbling of saliva, for this can neither be retained by the lips nor swallowed. The tongue shows fine fibrillation, and as it wastes it loses its point, becomes rounded, and is protruded with difficulty. Its surface becomes dimpled and faceted; in the end it consists solely of the covering mucous membrane, the glands and the fibrous tissue, and lies motionless in the floor of the mouth, resembling a crinkled mushroom. The muscles of mastication all become affected. The bite becomes feeble and the mouth cannot be opened against resistance. In the late stages the jaw drops and the mouth is constantly open. The combined weakness of tongue and buccinators makes it very difficult for the patient to keep his food between his teeth in mastication, and often he aids his disability by digital pressure upon the cheeks. Nasal regurgitation is not uncommon. The difficulty in swallowing is greatest with fluids, for these require quick action, and is next greatest with lumpy solids, for these necessitate powerful action. It is least with food of a porridge-like consistency, and this should be carefully borne in mind in feeding the patients.

The other muscles of the face are affected later and to a much less severe degree than is the orbicularis oris. It is as if there were a physiological selection on the part of the disease for the nervous mechanism subserving mastication and deglutition. Still in the majority of cases there is bilateral general facial weakness and wasting which, with the peculiar mouth and dropping jaw, produce a characteristic facies which can be instantly recognised. If the upper facial muscles are tested by raising the eyelid with the finger against resistance, invariably they will be found to be weak. Only in very rare cases does the atrophy extend to the oculo-motor muscles. As in the paralysis of the limbs, so also in bulbar paralysis, concomitant signs of both upper motor neurone and of lower motor neurone lesion may exist. When such tonic atrophy of the bulbar muscles is present, the symptomatology and clinical appearance are the same as have been above described for the simple atrophic form, with the exception that the jaw-jerk and the other muscle-jerks of the bulbar region, which are absent in the latter condition, are brisk in the tonic-atrophic form. And,

further, it must be remembered that the additional element of spastic paralysis adds greatly to the degree of the paralysis as a whole.

In less common cases of progressive bulbar paralysis the upper motor neurone lesion alone is in evidence, and the bulbar paralysis is purely spastic. Here the symptomatology as regards articulation, deglutition, etc., is the same, and the facial aspect identical with that of the simple atrophic and tonic-atrophic forms. The muscle-jerks are brisk. The appearance of the tongue, however, is quite different; it is smooth, narrow, stiff and drawn into a narrow compass by the spasm of the muscles composing it. It appears too small for so large a mouth. There is no fibrillation, and the muscles are nowhere wasted.

The muscles of the back of the neck, the splenius, complexus, etc., are not uncommonly the first muscles to be affected with the wasting of progressive muscular atrophy. There is increasing difficulty in extending the head, which drops forward, causing a characteristic attitude, which is associated with a constant overaction of the frontales which raise the brows to clear the line of vision when the head is dropped forward, so giving rise to a permanently furrowed brow. The loss of substance in the muscles of the back of the neck, together with the dropping forward of the head, causes the lower cervical and upper dorsal spines to stand out in undue prominence, and to give an appearance approximating to that of an angular curvature.

Primary affection of the lower extremities is much less common than that of the upper extremities, bulbar region or neck muscles. The anterior tibial and peroneal muscles are usually attacked first, and less commonly the quadriceps. The clinical type is that of flaccid atrophy in most of the cases. Tonic atrophy, which is so common in the upper limbs and in the bulbar region, is rare in the legs.

Wherever the site of commencement of progressive muscular atrophy may be, it invariably spreads to other regions, sometimes slowly and with periods of arrest which may last for years, sometimes with remarkable rapidity. The manner of spread is usually in terms of the contiguity of the affected elements in the nervous system; but it is sometimes in terms of the physiological association of the muscles, as is commonly seen in the bulbar forms of the malady. When the disease is definitely installed the appearance of fibrillation, in any muscles otherwise unaffected, is a sure sign that atrophy will shortly commence in those muscles.

According to the method of advance shown by the disease, cases of progressive muscular atrophy fall into two groups which it is important to distinguish. In the first group, the atrophy spreads locally and slowly and remains confined to one region of the body during most of the course of the malady. These cases are always of the simple atrophic type, and they usually survive a long time. Such cases, however, tend to become general just before the end. In contrast with the local type of the affection is the group in which the manifestations, commencing locally, spread within a comparatively short time to many parts of the body, or even become universal. The spread may be very rapid, and the end may occur in a few months, or it may be slower; but it is unusual for any of the cases forming this group to survive for more than 2 years. This group comprises (1) the generalised cases of simple flaccid atrophy; (2) all the cases of amyotrophic lateral sclerosis and (3) most of the bulbar cases.

*Fibrillation* is a most important symptom of the disease, and is an associate of the muscular atrophy. It precedes the wasting of the fibres, and is a sure herald of the advent of wasting in this disease. It ceases to occur when the muscle is completely wasted, and is not seen when the atrophy is not progressing. On account of the importance of fibrillation as a diagnostic sign of progressive muscular atrophy it is important here to consider those other conditions in which it is met with clinically. It occurs in syringomyelia and in peroneal atrophy, but only when the muscular atrophy is progressing, and, therefore, it is only an occasional symptom in either disease. It is often very marked in cases of interstitial neuritis (sciatica, etc.). It

occurs in a most magnified and conspicuous form in certain conditions of gastro-enteritis, and is presumably due to an intoxication, and to this form of fibrillation the term "myokimia" has been applied. It is not met with in polyneuritis, poliomyelitis, myopathy, nor in the common gross lesions of nerve trunks, nerve roots or spinal cord.

The *electrical reactions* of the affected muscles vary according to the degree of degeneration. Since normal and degenerate fibres are stimulated side by side in the affected muscle, there will be some lowering of the response to faradism with a tendency to a polar change. This is known as the "mixed reaction" and it is common to all diseases in which muscle degenerates fibre by fibre. Faradic excitability lessens as more of the muscle fibres degenerate, and when degeneration is complete all electrical excitability is lost. In tonic atrophy the excitability of the affected muscles to direct mechanical stimuli, such as percussion, is increased so long as any living muscle remains.

*Contractures* are conspicuous by their absence in this disease, which is thus strongly contrasted with peroneal atrophy and some other muscular atrophies. If the atrophy becomes complete in a whole limb the end-result is that the limb is flail-like and without contracture.

*Mental alterations* are constantly present in the cases in which the bulbar region is affected. Emotional instability and hyperexcitability are the usual change. The patient is easily excited to tears or to laughter by trivial causes, and when so excited cannot control his expression of emotion. He himself feels little joy or grief during the paroxysms of laughing or crying.

*Sphincters*.—In the majority of the cases these are not affected, but every now and then dysuria in any of its forms occurs, and it may occur early in the course of the malady, and it may be severe. Loss of sexual power is very common.

*Reflexes*.—The reflexes are modified in this disease, on the one hand by spasticity, when this is present, and, on the other, by the muscular atrophy which may prevent response in the affected muscles. The pharyngeal reflex in bulbar cases is usually brisk, notwithstanding the statement to the contrary, which most writers upon this subject have recorded; but the response is not the normal response, involving all the muscles concerned in deglutition, for these are atrophied and paralysed; it is confined to the constrictors of the pharynx and the muscles of the palate, with the feeble co-operation of such of the somatic bulbar muscles as are still able to act. The plantar reflexes are usually of the extensor type when the legs are spastic; but this does not always obtain. Similarly, the abdominal reflexes do not disappear so constantly or so early as is the case in disseminated sclerosis, for example, and they may persist when the legs are markedly spastic and extensor plantar responses have appeared. In cases of tonic atrophy the tendon reflexes are everywhere increased, even in regions where the atrophy is severe, and in this type of the malady they never disappear. The same increase of the muscle-jerks occurs in the purely spastic cases. In simple atrophic cases the tendon-jerks disappear *pari passu* with the wasting of the muscles.

*Cerebrospinal fluid*.—The cerebrospinal fluid is always quite normal by all the tests at present in vogue. It does not usually contain more than one cell per c.mm., and no change has been detected in its chemical constitution.

*Diagnosis*.—The malady has to be distinguished from the many conditions in which progressive weakness and wasting of the muscles occur, from those in which muscular wasting and spasticity are conspicuous clinical features, and lastly from other diseases, in which bulbar symptoms are early evidenced. Injury of the cervical enlargement of the spinal cord gives rise to a limited degree of wasting in the upper limbs, and spasticity of greater or less intensity in the lower limbs (see p. 1541). The wasting in the upper limbs becomes apparent some weeks after the injury and affects the muscles corresponding to the injured segments of the cord, which are

commonly those of the forearms and hands. But weakness of these muscles and the spastic weakness of the legs are maximal immediately after the injury, and power usually shows an improvement during the succeeding weeks or months, whereas in progressive muscular atrophy the weakness, wasting and spasticity come on insidiously and progress steadily. It must be realised that, although bony injury is commonly present, injury of the cervical cord may occur without any fracture or dislocation of the cervical spine. Furthermore, a moderate degree of weakness of the limbs may escape observation while the patient is in bed after an accident, or they may be ascribed to other causes, and so the signs resembling amyotrophic lateral sclerosis may not be discovered until several weeks after the occurrence of the lesion responsible for them. Inversion of the supinator jerk (see p. 1541) is a common sign in cases of injury of the cervical enlargement, but rarely, if ever, occurs in progressive muscular atrophy. Syphilitic amyotrophy (p. 1470) may be indistinguishable from progressive muscular atrophy except by the results of the Wassermann reactions in the cerebrospinal fluid and blood. Peroneal muscular atrophy very closely resembles progressive muscular atrophy, in that slow wasting and fibrillation of the muscles are the chief clinical features. The points which distinguish the two conditions are that peroneal atrophy is often a familial disease, and is apt to commence in childhood when it is unusual for progressive muscular atrophy to begin. The location of the atrophy is peculiar, and when well marked in the periphery of all four limbs, as is common in this disease, cannot be confused with progressive muscular atrophy since the latter disease never has this distribution. Syringomyelia is easily distinguishable by the early and striking loss of pain and temperature sensibility. Cervical rib not uncommonly produces atrophy of the intrinsic muscles of the hand, and, though this is usually confined to one hand, it may be bilateral. Further, it is exceptional for the atrophy to involve all the small hand muscles simultaneously, or equally. It picks out the opponens pollicis first and most severely, and is not uniform for all the hand muscles, as in progressive muscular atrophy. Pain in the distribution of the eighth cervical and first dorsal roots, and some loss of sensibility, may be present. The atrophy remains local, and is never accompanied by fibrillation. The abnormal rib is easily discoverable on radiographic examination. It must be borne in mind that cervical ribs are not uncommon, and that their presence does not necessarily prove the cause of atrophy of the hand muscles, for cervical ribs may be present in the subjects of progressive muscular atrophy, syringomyelia or any other disease.

The diagnosis of progressive muscular atrophy from the primary muscular dystrophies seldom causes serious difficulty. The latter occur, in general, at a much earlier age and several members of a family may be affected; the incidence of the wasting is almost invariably on the proximal muscles, the weakness is out of proportion to the apparent wasting, fibrillation is absent, and the progress of the disease is very much slower than that of progressive muscular atrophy. Dystrophia myotonica is at once separated from progressive muscular atrophy by the myotonus, when this latter symptom is present. When myotonus is absent, the characteristic wasting of the sternomastoids and of the muscles of the thighs, the age of the subject, and sometimes the presence of cataract should suggest the diagnosis. Arthritic muscular atrophy occurs in the regions of joints which show easily recognisable disease. Fibrillation does not occur, nor are there alterations in the electrical excitability of the wasted muscles.

Lesions of peripheral nerve trunks may be diagnosed by the history of a local cause, by the discovery of a palpable local lesion upon the course of the nerve, and by the confinement of the atrophy to the distribution of one particular nerve, while pain and sensory loss often occur in that same distribution.

Lesions of the nerve roots, and especially those produced by pachymeningitis and by neoplasm in the vertebræ may cause signs and symptoms so closely resembling those of the more rapid forms of progressive muscular atrophy, as to render correct

diagnosis very difficult. Such a lesion in the cervical region, for example, may give rise to wasting of the hand and forearm muscles, and a spastic condition of the legs, resembling exactly a condition of amyotrophic lateral sclerosis, without deformity or rigidity of the spine, and without pain or sensory loss. In such cases of difficulty the course of a little time will bring the advent of the conclusive symptoms of a local pressure lesion. It is important in this connection to remember that pressure upon the spinal cord results in hyperalbuminosis of the cerebrospinal fluid, and if the lesion causing the pressure is syphilitic there is likely also to be lymphocytosis in that fluid, neither of which conditions is found in progressive muscular atrophy.

Diagnosis is most difficult in those cases where spasticity in the limbs is the first sign of progressive muscular atrophy, and where such spasticity precedes the appearance of any muscular atrophy by a long time. If it be clearly borne in mind that spastic paralysis may be the earliest and for a time the only sign of progressive muscular atrophy, and that among the many diseases of the nervous system which commence with the same clinical picture of spastic paralysis a certain diagnosis cannot be made until further distinguishing signs appear, error will be avoided. The importance of the examination of the cerebrospinal fluid in doubtful cases cannot be too strongly emphasised.

**Course and Prognosis.**—The nature of the disease is to progress, and to extend its area of invasion until a fatal issue is reached. The progress may be rapid, and the end may be reached in a few months, or it may be slow, and several years may elapse before death occurs. The local types of progressive muscular atrophy of slow onset are the most gradual in their development, and these are often characterised by periods of arrest in the progress of the disease. The generalised simple atrophic type of the disease is the most rapid, especially when it commences with severe initial flaccid paralysis without atrophy.

In the bulbar types of the disease, and in the common type of amyotrophic lateral sclerosis, the course is, for the most, steadily progressive. Every type will show, however, upon occasion, exacerbations and remissions, and the exacerbations are the most important, and in the bulbar types may bring about the end in a few hours. Of particular interest are rapid extensions of a flaccid paralysis, which may occur in a few hours, and which resemble, and indeed are identical with, onset of the disease with initial flaccid paralysis without atrophy, which has been already described. Whatever type of the disease be present, it tends in the end to spread and to become general.

Involvement of the respiratory muscles or severe bulbar symptoms, and the pulmonary complications which may accompany either condition, may bring about the fatal issue. It is usual however for death to occur in a manner which is common to so many degenerative nervous diseases; a rapid increase of the paralysis is associated with an increasing lethargy, which soon deepens into a rapidly fatal coma. It is uncommon for death to occur from intercurrent maladies. The average tenure of existence after definite signs are present is under 1 year in the generalised flaccid type, and it may be as short as 2 months. Bulbar symptoms are not generally survived for more than 12 months. Localised cases of simple atrophy may live for many years. Some of the patients in whom a positive Wassermann reaction is found improve, and the disease is sometimes arrested by antisiphilitic treatment.

The progressive character of the disease renders the prognosis grave in every case. There are some cases occurring in middle life, which resemble cases of progressive muscular atrophy of local distribution and slow course, which become finally arrested or even recover; the true nature of such cases is doubtful, but it is probable that they are allied to polyneuritis.

In amyotrophic lateral sclerosis the average duration of life is seldom more than 3 years from the onset. When bulbar symptoms are present the average duration is under 2 years. In the generalised cases the average duration is under 1 year. Widely

spread fibrillation in muscles, which are neither weak nor wasted, is the constant herald of generalisation, and renders the immediate prognosis serious. In cases where syphilis is present the prognosis is more favourable, and there is even a possibility of arrest and improvement if energetic treatment of the associated condition is provided. Rapid extension of the weakness, the advent of bulbar symptoms, involvement of all the respiratory muscles, and especially general asthenia and drowsiness are the signs which usher in the fatal result.

**Treatment.**—This malady seems to be entirely uninfluenced by any treatment that has hitherto been adopted. At one time dramatic claims were made in respect of vitamin E (tocopherol acetate), given in doses of 3 mg. thrice daily. This was said to arrest wasting and weakness and in early cases to effect rapid improvement. These claims, however, have proved illusory. It remains, therefore, to secure favourable conditions of life for the patient, and to maintain the general health in as perfect a state as possible. Massage and passive movements are useful as giving bodily comfort to the patient, and satisfying him that something is being done for him. In bulbar cases, the dysphagia must be aided by avoiding liquids and solids, and by serving all the articles of diet in pultaceous form. Salivation, which is so troublesome in this condition, may be greatly helped by the administration of hyoscine or belladonna by the mouth.

## PERONEAL MUSCULAR ATROPHY

**Synonyms.**—Charcot-Marie-Tooth Type of Muscular Atrophy, Neuritic Type of Muscular Atrophy.

**Definition.**—This is an absolutely distinct and peculiar form of muscular atrophy, with a frequent tendency to occur in several members of the same family. It usually commences in mid-childhood, and after progressing for some 20 years or less, comes to a final arrest. The atrophy always commences in the intrinsic muscles of the feet, and is throughout strictly distal in distribution. The muscles of the face and trunk and the proximal muscles of the limbs are never affected. The atrophy leaves a peculiar elastic fibrosis in the affected muscles, so that the incapacity caused by this disease is much less than in any other form of muscular atrophy of like degree. Sensibility is often slightly affected, and there may be deep sensory loss. The essential morbid anatomy is a primary neurone atrophy of the anterior horn cells and of some of the afferent neurones in Clarke's column.

**Ætiology.**—The disease usually commences between the fifth and tenth years of childhood, but it may appear as late as the fourth decade of life. Males and females are both affected. Heredity plays an important part in the incidence, although isolated sporadic cases are not uncommon. It may exhibit every type of inheritance. The malady often occurs in families, and has been traced through five generations; it may skip a generation and then reappear.

**Pathology.**—The anterior horn cells of the affected regions show a slowly progressive atrophy and disappearance, with corresponding atrophy of fibres in the peripheral nerves. The cells of Clarke's column show signs of degeneration, as do also some of the fibres of the posterior columns of the spinal cord, and especially those of the postero-lateral column. Slight degeneration in some of the fibres of the pyramidal tracts is usually found. The affected muscles show a simple atrophy of the muscle fibres, indistinguishable from that seen when a motor nerve is divided. There is a simple shrinking of the fibres, which stain progressively and more and more deeply with hæmatoxylin, lose their striation, and finally disappear. Secondary fibrotic changes accompany the atrophy, together with sclerosis of the arteries of the muscle.

**Symptoms.**—Muscular atrophy dominates the clinical picture of this malady.

It is strictly distal in distribution, and this feature will serve to distinguish peroneal atrophy from any other form of muscular atrophy. This is to say it does not affect one particular muscle, but the distal ends of all the muscles below a certain level on the limb, leaving the proximal ends of the muscles normal, and it advances up the limb inch by inch, the separation of the wasted portion of the muscle from the normal portion being always transverse to its length. In other words, the muscle fibres seem to waste in terms of the length of the spinal axons which supply them. The wasting commences always in the intrinsic muscles of the feet, and hollowness of the instep and thinness of the feet, together with retraction of the toes and the difficulty which the pes cavus so produced entails in fitting boots, first draw attention to the disease. As the process advances, the lower segments of the anterior tibial, peroneal and calf muscles become affected, and the limb is subsequently involved until the lower third of the thigh is reached, at which stage the disease is invariably arrested. This slow spread of the atrophy from the distal towards the proximal portion of the limb, gives rise to a unique and characteristic feature in the appearance of the legs at the several stages of the disease. As an example, the complete atrophy of all the muscles below the middle and a well-developed musculature in the upper half of the leg, give rise to the inverted "fat bottle" calf. When the atrophy has involved the lower third of the thigh, the lower end of the femur, bare of muscle and covered only by skin and tendons, contrasts strongly with the well-developed muscles of the upper thigh, and causes the thigh to resemble an inverted champagne bottle.

Some years after the atrophy has become marked in the lower extremities, and in the usual run of cases just before the age of puberty, the intrinsic muscles of the hands, and first those of the thenar and hypothenar groups, begin to waste, and this wasting may extend as high as the middle of the forearm. It must be borne in mind that the disease may become arrested at any period of its spread, and especially that the upper extremities often escape altogether. With the exception of the lower part of the thighs, the proximal segments of the limbs do not become involved, and the muscles of the head, neck and trunk remain unaffected.

The affected regions of the muscles waste absolutely, and leave a very elastic fibrous tissue. The electrical excitability in the wasted regions becomes first lowered and then lost, and, in the earlier stages, may show a mixed reaction, in which there is lowering of excitability to faradism, with a tendency to an inverted polar reaction. Fibrillation of the muscles is an important sign. It is seen only when the disease is progressing, and in the muscles which are obviously wasting. It is never general, as in some cases of progressive muscular atrophy, and since peroneal atrophy is at times advancing and at other times stationary, fibrillation may be in one case conspicuous and in another never seen. It disappears entirely when the progress of the malady becomes finally arrested, and is, therefore, useful as a clinical indication of active advance of the disease. Contractures always occur, and from the nature of the distribution of the atrophy are necessarily confined to the feet and the hands. In the feet, pes cavus with retracted toes is the rule; but sometimes, and in some stages of the disease, the feet and toes may be dropped and the feet inverted. The sphincters are unaffected. The ankle-jerks are diminished or lost in proportion to the wasting of the calf muscles. In the final arrested stage they are usually lost. The knee-jerk is always retained and is usually brisk. The plantar reflexes are usually lost early so far as any response in the foot is concerned, but some response in the upper thigh muscles, upon stimulating the plantar region, often remains. Pain, tenderness and cramp are entirely absent. Conspicuous loss of sensibility is uncommon, but slight loss of deep sensibility, loss of the vibration sense and relative tactile loss may often be detected upon careful examination: but in rarer cases all forms of sensibility may be severely affected, or even entirely lost. Perforating ulcers may be met with upon the soles of the feet, and are explained by the thinness of the feet and their deformity, which, coupled with the clumsiness of the use of the feet, lead to the formation of

severe corns which break down into perforating ulcers. Loss of sensibility also is a factor in their production.

The most striking of all the clinical features of peroneal atrophy is the comparatively slight disability caused by the wasting of the muscles and consequent paralysis, and even the sensory loss, when it is present.

**Course.**—The course is irregularly progressive for a number of years only, and the advance of the disease ceases usually in the third decade of life. Exacerbations of the weakness are likely to be followed in every case by considerable improvement, owing to the secondary fibrosis in the muscles.

**Diagnosis.**—Peroneal atrophy in the early stages is easily confused with progressive muscular atrophy, in that wasting of muscles and fibrillation are the conspicuous features. The onset usually in childhood and the fact that the feet are affected first, the peculiar distal distribution and the presence of any familial incidence, are important. But the only distinction which is absolute is the distribution, for progressive muscular atrophy may begin in childhood and peroneal atrophy may not appear till after middle life, and often familial history is absent in the latter malady. In the course of time the diagnosis always becomes clear, for progressive muscular atrophy never keeps to the classic distribution of peroneal atrophy, nor is it followed by the peculiar fibrosis which characterises the latter.

Dystrophia myotonica when commencing in the peroneal muscles may for a time closely simulate peroneal atrophy. The presence of the least sign of myotonia, the involvement of the face and the atrophy of the sternomastoids, will establish the diagnosis.

The usual forms of myopathy are at once separated from peroneal atrophy by the distribution of the muscular weakness and wasting, which in the former group of maladies is conspicuously upon the face, trunk and proximal muscles of the limbs, and in the latter upon the distal muscles. Peripheral neuritis is more rapid in its onset, and is apt to be associated with marked sensory disturbances, both objective and subjective, and the paralysis is in terms of individual muscles, which is not the case in peroneal atrophy.

**Treatment.**—The general health should be carefully maintained, and the nutrition of the affected muscles aided by the application of massage. Care must be taken, on the one hand, to avoid over-fatigue of the affected muscles, and, on the other, to ensure such regular exercise as is compatible with their capacity. Bicycling, for example, since it employs chiefly the thigh muscles, is a better form of exercise for these patients than is walking. In no circumstances should tenotomies be performed for the deformity of the feet, for such measures tend to destroy the effect of the conservative fibrosis, so essential to the production of a useful limb. The use of heavy mechanical supports is to be avoided above all things. Light, well-fitting boots, so as to interfere as little as possible with the exercise of the damaged muscles, are essential.

## PROGRESSIVE SPINAL MUSCULAR ATROPHY OF CHILDREN

**Synonym.**—The Werdnig-Hoffmann Disease.

**Definition.**—This is a malady of the first year of infancy, often incident upon several children of the same parents, and characterised by the gradual development of progressive muscular weakness and atrophy, which affects the proximal muscles first and most, increases to a complete paralysis of trunk and limbs, and finally affects the bulbar muscles. The disease is invariably fatal in from a few weeks to several months. The most striking pathological changes are a progressive degeneration and disappearance of the ventral horn cells of the spinal cord, and of their analogues in the brain-stem.

**Ætiology.**—In some of the cases the paralysis is noticeable at the time of birth, and the disease is obviously of pre-natal development. In others the children are quite healthy at birth, and the disease develops some time during the first year of life, and most frequently within 3 weeks of birth. Though sporadic cases may be met with, yet in the majority of instances several children of the same mother are affected. Both the pre-natal cases and the post-natal cases may be met with among the children of the same mother. The sexes seem to be equally affected. No maternal ill-health during pregnancy has been noticed, and nothing is known about any other ætiological factor.

**Pathology.**—The most extensive changes are found in the ventral horn cells throughout the spinal cord and brain-stem, and at many levels no normal cells whatever are to be seen. Tigrolysis, swelling and glassiness of the cells, extrusion of the nuclei, disappearance of the dendrites, shrinking of the cells and final disappearance is the sequence of the changes. Degeneration of the anterior roots and of the peripheral motor nerve fibres consequently occurs. These changes are not confined to the lower motor neurones, for in some cases examination by the Marchi method shows extensive degeneration throughout the posterior columns of the cord, indicating that lower sensory neurones were also considerably affected.

The muscles show intense degeneration with hypertrophy of some fibres and atrophy of most of the fibres, waving, moniliform shape, hypernucleation of the spindles, general nuclear increase and fibrosis.

**Symptoms.**—In the cases which are pre-natal, the malady is noticed at the time of birth on account of the tonelessness, flaccidity and the poorness of movement in the trunk and proximal muscles of the limbs. In the post-natal cases there is a gradual onset of similar weakness and flaccidity in the trunk first, and in the limbs afterwards, which usually commences within 6 weeks of birth, but which may not appear until towards the end of the first year of life. The weakness seems always to be least marked in the periphery of the limbs, where curious, slow, involuntary movements of the fingers and toes have been noted in many of the cases. The paralysis is followed by a rapid and extensive wasting of the muscles, accompanied by occasional fibrillary twitchings. Since these children are not only well nourished, but often put on much fat during the illness, wasting of the muscles may not be apparent on inspection or palpation. It can, however, immediately be detected by radiography, which distinguishes sharply between fat and muscle.

As the malady progresses the trunk muscles become completely paralysed, the intercostal muscles being always paralysed before the diaphragm. The limbs become progressively weaker, and, lastly, bulbar paralysis supervenes in those cases where death has not already occurred from respiratory paralysis. The reaction of degeneration is present in the affected muscles. Sensibility may be unimpaired but in several of Collier's cases there was conspicuous loss of pain sensibility over the limbs and trunk. The sphincters are unimpaired until the very last stages of the disease. The superficial and deep reflexes are lost. The ocular muscles are not affected, and intelligence is preserved throughout.

**Diagnosis.**—The peculiar and striking features of the disease make the diagnosis easy, if the symptomatology be known. Amyotonia congenita presents the same helplessness and flaccidity of trunk and limbs as does the Werdnig-Hoffmann disease, and further resembles it in being sometimes congenital, and sometimes having an onset very early in life. In amyotonia congenita, however, the paralysis is not complete, and it tends to improvement and not to progressive increase. Contractures also occur, which are not found in the Werdnig-Hoffmann disease, and, lastly, the definite spinal cord changes of the latter malady are not found in the former. Greenfield, however, considers that amyotonia congenita and Werdnig-Hoffmann paralysis are different aspects of a single disease.

**Course and Prognosis.**—The course is invariably progressive, and is more rapid

the earlier in life the disease commences, and it is most rapid of all in the pre-natal cases, which are usually fatal within a few weeks. With an onset some weeks after birth, life is usually continued for several months, and a few cases have been reported with an onset towards the end of the first year, in which death has been delayed until the third or fourth year.

**Treatment.**—No treatment is known to influence the course of the malady.

## DISORDERS OF THE PERIPHERAL NERVES

### LOCAL LESIONS OF NERVE ROOTS AND NERVE TRUNKS

Individual peripheral nerves may be damaged by a large number of agencies. Trauma may affect them in a variety of ways. Direct penetration by a sharp body such as a knife or glass, or the passage of a fragment of a projectile may sever the nerve completely or partially. Injury by a blow with a blunt agent or severe commotion in surrounding tissues, such as occurs with the passage of a projectile near the nerve, may destroy the axons without interrupting the continuity of the more resistant medullary sheaths and perineurium. Recovery of such a nerve requires the growth of new axons down the surviving medullary sheaths. Similar injuries of less intensity may temporarily abrogate the function of the nerve but be followed by recovery of function in a matter of hours or days. For these three degrees of nerve injury Seddon has suggested the names neurotmesis, axontmesis and neurapraxia respectively. Nerves may also be injured by trauma of a less violent but more sustained character as is seen in the common varieties of pressure palsy such as "Saturday night paralysis", crutch palsy, palsies from pressure of plaster and other splints and chronic overstretching as in the case of the ulnar nerve. Peripheral nerve lesions may follow a variety of general infections such as pneumonia, dysentery and streptococcal illnesses. Nerves may be involved in specific inflammatory processes such as leprosy. Finally they may be involved in new growths. The most important example of this is infiltration with carcinoma from a neighbouring focus, but nerves may be the site of isolated neurofibromata or multiple lesions in cases of Von Recklinghausen's neurofibromatosis.

#### PHRENIC NERVE

This nerve supplies the diaphragm. Paralysis results most often from disease of the spinal cord, but the roots may be implicated in disease of the spine, and the trunk may be injured, in its course through the neck and thorax, by wounds or tumours. Bilateral paralysis occurs in lesions of the cord and spine, and in polyneuritis especially of the diphtheritic and acute infective varieties. Other causes usually affect one side only. When the diaphragm is completely paralysed, the normal inspiratory protrusion of the upper part of the abdomen disappears, or is replaced by retraction of this part with each inspiration. During rest, so long as the lungs are healthy, the respiratory rate does not increase, but if bronchitis or pneumonia arises as a complication, or if the patient exerts himself, the diminished reserve of respiratory power is seriously felt. When one nerve only is affected the diaphragm does not move on that side, but becomes permanently elevated as a result of collapse of the base of the corresponding lung. This is rarely detected by observation of the abdominal movements, but is easily seen on the radiograph screen. It produces no discomfort.

#### THE LONG THORACIC NERVE

This nerve supplies the serratus anterior muscle. When all the fibres of this muscle contract, the scapula moves upwards, forwards and outwards. It contracts

with the pectoralis major in the action of pushing forward the point of the shoulder and in the rapier-thrust movement. It also assists the deltoid in raising the arm. When it is paralysed alone, the position of the scapula at rest is unaltered, but if the trapezius and the rhomboids are paralysed as well the scapula drops, and its lower angle is displaced inwards. Paralysis of the serratus anterior is best demonstrated by causing the patient to hold the arms outstretched before him. The arm is not raised so high on the affected as on the normal side, because the scapula is not fixed and the deltoid works at a disadvantage. Viewed from behind the deformity is characteristic. The vertebral border of the scapula stands out prominently and the hand can be pushed between this bone and the thorax—"winged scapula". On raising the arm from the side, there is difficulty in attaining the horizontal position, but the winging of the scapula is less apparent.

The nerve may be damaged by carrying heavy weights on the shoulder, by falls or blows on the shoulder, and by continued muscular effort with the raised arm. The nerve may be injured alone in gunshot wounds, but as a rule it is associated with lesions of the brachial plexus. In addition, a serratus anterior palsy may develop suddenly in an otherwise healthy person after exposure to cold, or as part of a rare reaction to the administration of serum or antitoxin. In such neuritic cases and in the cases caused by compression, severe neuralgic pains in the neck precede the onset of paralysis. Recovery is always very slow and the defect may be permanent.

#### BRACHIAL PLEXUS

The brachial plexus may be injured by stabs in the neck, by penetrating missiles, by dislocation of the shoulder or fracture of the clavicle, or by pressure of a tumour, aneurysm or cervical rib. Further, the nerves may be torn by forcible dragging on the arm in accidents or during delivery. In most cases the lesion is partial and the symptoms conform in the main to one of the following types:

*Upper plexus paralysis (Erb's palsy).*—This results from an injury to the fifth and sixth cervical roots. The muscles paralysed are: biceps, deltoid, brachialis, brachioradialis (supinator longus), supraspinatus, infraspinatus, rhomboideus, subscapularis, clavicular portion of pectoralis major, serratus anterior, latissimus dorsi, teres major. The arm cannot be flexed at the elbow (flexors of forearm), nor raised and abducted (deltoid). The movements of the wrist and fingers are not impaired. Adduction of the arm is weak (pectoralis major), and rotation is feeble or absent (spinati). On attempting to oppose the shoulders, the scapula on the affected side passes farther from the middle line (rhomboideus). The hand of the affected side cannot be placed on the buttock of the sound side (latissimus dorsi).

The reaction of degeneration is often complete in the deltoid and flexors of the forearm and nearly so in the spinati. It is usually incomplete in the other muscles. Sensation is diminished or lost along the outer border of the whole limb immediately after the injury, but improvement sets in rapidly. For some time the patient experiences pins and needles and burning sensations in the affected area, which last longest in the thumb and index finger. The biceps reflex is lost.

*Lower plexus paralysis (Klumpke's palsy).*—This results from a lesion of the eighth cervical and first dorsal roots, or of the common trunk of the median and ulnar nerves. The intrinsic muscles of the hand and the flexors of the wrist and fingers are paralysed, and the inner border of the forearm and hand is anæsthetic. When the roots are damaged sympathetic fibres may be implicated with the production of myosis, narrowing of the palpebral aperture, enophthalmos and alterations in sweating on the face, neck, arm and upper part of the chest on the affected side.

*Middle plexus paralysis.*—This form of paralysis is a common result of gunshot injuries of the plexus. It affects the muscles supplied by the radial and axillary nerves—posterior cord. As the nerve to the latissimus dorsi arises from the same cord,

this muscle is often paralysed as well. In addition to these simple types, more complicated paralyses occur, in which various parts of the plexus are injured together.

*Paralysis of the medial cord of the plexus.*—Atrophy is confined to the intrinsic hand muscles, and the sensory loss is confined to the hand.

*Incomplete lesions of the brachial plexus* show a remarkable tendency to spontaneous recovery. In many cases recovery is complete in 6 months to 2 years, in others it is partial, and some muscles remain paralysed.

#### THE RADIAL NERVE

Owing to its long course, its position in relation to the humerus, and its peculiar vulnerability to compression, paralysis of the radial nerve is one of the commonest peripheral nerve palsies; although it is a mixed nerve, containing sensory, motor and vasomotor fibres, the symptoms of an injury are almost entirely motor. In the upper arm the nerve supplies the triceps and the anconeus, in the forearm the supinators, the extensors of the wrist and fingers, and the extensors and long abductor of the thumb.

Injury to the nerve is followed by dropping of the wrist and fingers. The wrist and the first phalanges are flexed. The flexion is limp and easily reducible.

When the lesion is in the axilla the whole of the *triceps* is paralysed, and extension at the elbow is lost. Occasionally in wounds of the posterior aspect of the arm the nerves to the triceps are injured, whilst the main trunk escapes. The patient is then able to extend the arm powerfully by means of the anconeus, but if he is made to raise the elbow as high as possible with his fingers on the point of the shoulder, extension of the bent forearm is impossible.

In most cases the nerve is injured in the middle third of the arm and the triceps escapes, but the brachio-radialis and all the extensor muscles in the forearm are paralysed. Partial paralyses, such as are seen in lesions of the median and ulnar nerves, are very rare. The brachio-radialis is not a supinator. Its action is to flex the forearm, whilst the hand is in a position intermediate between pronation and supination. Paralysis of this muscle is detected by the absence of contraction when the pronated forearm is flexed against resistance. Owing to paralysis of the *supinator* supination is abolished. During the movement of flexion of the forearm the biceps acts as a supinator, and during extension the external rotators of the shoulder correspond, though feebly.

Paralysis of the *extensors of the carpus* abolishes both extension and lateral movement at the wrist. The flexors of the carpus play no part in lateral movements. The *extensors of the fingers* extend the first phalanges only. Extension at the distal joints is carried out by the lumbricals and interossei. Paralysis of the *extensors and long abductor of the thumb* renders abduction of the thumb and extension of the phalanges impossible. On attempting to abduct the thumb, it passes no farther than the radial border of the hand. In some cases, the second phalanx of the thumb can be feebly extended by the muscles of the thenar eminence.

Many muscles not supplied by the radial nerve work at a disadvantage when the extensors are paralysed. These defects must not be mistaken for signs of injury to other nerves. Owing to the flexed position of the hand the grasp is feeble, but if the wrist is extended passively the grasp is improved. The patient cannot make a fist properly, as the thumb does not oppose the index finger and the fingers cannot be flexed into the palm, until the thumb has been moved aside by the sound hand. The movements of the interossei in abducting and adducting the fingers are also feeble while the wrist is flexed, but are much stronger when the hand is resting flat on a table with the wrist and fingers extended. The complete reaction of degeneration is often found in all the paralysed muscles from the onset. Atrophy becomes obvious in a month or two. Its extent and severity give important evidence for prognosis.

**Sensory disturbances.**—Subjective symptoms are rare. In a few cases, paræsthesiæ are felt on the posterior aspect of the forearm and on the dorsal aspect of the thumb. They are of brief duration, and are commoner with partial than with complete lesions. Causalgia is almost never seen in lesions of this nerve. Sensibility to light touch, superficial pain and temperature is impaired over a small area on the radial border of the hand, including the proximal joints of the thumb and the first two fingers. The defect is often very slight, and is only discovered on very careful examination. Deep sensibility is rarely affected. Considering the extensive distribution of the superficial branch of the radial nerve, it is rather surprising that the sensory disturbances are so slight, when the nerve is injured above the origin of this branch.

As a rule, the brachio-radialis recovers first, then the extensors of the wrist, then the extensors of the middle, ring, little and index fingers in this order, and the extensors and abductors of the thumb last of all. On palpation of the muscles during attempted extension, contractions can be felt before any movement is produced. Other signs of impending recovery are the disappearance of automatic pronation and of the flail-like drop of the hand, also diminution of automatic flexion of the fingers after passive extension. Recovery of movement is complete when the patient is able to extend the wrist and all the fingers simultaneously or separately. After this becomes possible, restoration of power is rapid.

#### THE MEDIAN NERVE

Whilst the clinical individuality of the radial nerve is shown in the preponderance of motor symptoms and in the uniform completeness of the paralysis that follows an injury, that of the median is seen in the frequency of partial and especially of painful lesions. Isolated palsy of this nerve is infrequent except as a result of gunshot wounds and other injuries.

**TOTAL PARALYSIS.**—The muscles paralysed are the pronators, the radial flexor of the wrist, the flexors of the fingers except the ulnar half of the deep flexor, most of the muscles of the thenar eminence (opponens, abductor brevis and outer head of the flexor brevis pollicis) and the two radial lumbricals. Stated briefly the symptoms are: inability to flex the phalanges of the index finger and the second phalanx of the thumb; difficulty in flexing the phalanges of the middle finger; defective opposition of the thumb. The appearance of the hand in total lesions is fairly constant. The hand inclines to the ulnar side, the index and middle fingers are more extended than is normal, and the thumb lies on a level with the fingers—the ape-hand.

**Pronation** is incomplete and defective. The patient tries to overcome the defect by rotating the whole limb at the shoulder. Paralysis of the *flexors of the wrist* is seen when an attempt is made to flex against resistance. The tendon of the ulnar flexor alone stands out, and the hand is drawn towards the ulnar side. Even at rest, the flexor tendons are more prominent on the sound than on the affected side.

**Flexion of the fingers** is good in the two ulnar fingers, though weaker than normal. The index cannot be flexed at all, and the third finger only incompletely. Flexion at the proximal joint is usually good in all the fingers including the index, and flexion at this joint with extension at the last two joints is usually well done by the interossei and lumbricals. If the proximal phalanx of the thumb is immobilised, it will be seen that flexion of the terminal phalanx is abolished, owing to paralysis of the *flexor longus pollicis*.

Paralysis of the *thenar muscles* renders opposition and abduction of the thumb defective. By means of the adductor the thumb can be drawn into the palm, but as the radial fingers cannot be flexed nor the thumb opposed, it is impossible to place the tip of the thumb on the tips of the fingers. Atrophy of the muscles becomes obvious in a few weeks. The outer part of the thenar eminence is flattened, and the bulk of the muscles arising from the internal condyle is greatly diminished.

**Sensory disturbances.**—In almost every case there is complete anæsthesia to all forms of sensation in the two terminal phalanges of the index and middle fingers. The skin outside this area may be unaffected even in complete lesions, but in most cases sensibility is diminished in the terminal phalanx of the thumb, and to a less extent over the remainder of the radial half of the palm, including the radial side of the ring finger. The stereognostic sense is lost in the outer fingers. This defect, together with the loss of power, renders the thumb and index finger useless, and makes paralysis of the median the most serious single nerve lesion of the upper limb.

**Vasomotor and trophic changes.**—In many cases the skin in the distribution of the median nerve is red, dry and chapped, and the nails white or purple, and atrophy occurs in the pulp of the affected fingers.

**Recovery** is slow and is rarely complete. Sensation begins to return before power, but the stereognostic sense is often defective, long after movement in the fingers has returned. The pronator and the flexors of the wrist recover first, then the flexors of the thumb and middle finger. Flexion of the index finger and opposition of the thumb, if it is regained at all, remains defective for several years. In searching for signs of recovery, care must be taken lest some "trick-movement", due to contractions of healthy muscles, is misconstrued. For example, when told to flex the terminal phalanx of the thumb, the patient first over-extends and abducts, and then relaxes suddenly. The terminal phalanx then makes a slight passive movement of flexion, which may be mistaken for true active flexion. Recovery is complete when the patient is able to make a good fist with the fingers flexed well into the palm, and the thumb pressed firmly upon the dorsal aspect of the second phalanx of the middle finger.

**PARTIAL LESIONS.**—Partial paralysis of the median nerve is much commoner than the complete form.

**Motor symptoms.**—Flexion of the index finger and opposition of the thumb are most impaired. The flexors of the middle finger and of the terminal phalanx of the thumb may suffer also, but to a less degree, whilst the pronators and the flexors of the wrist often escape entirely.

**Sensory symptoms.**—Apart from the painful lesions to be mentioned later, sensory troubles are usually slight in partial lesions. Anæsthesia is rare, but sensibility to all forms may be diminished in the areas mentioned under complete lesions.

**Vasomotor symptoms.**—The skin is often cyanosed in the distribution of the injured nerve, and it may perspire more freely than in healthy parts. These changes are more distinct when the paralysis is complicated by a vascular lesion.

**Recovery** is naturally more rapid than in complete lesions. The order in which the muscles recover and the tests for complete return of function have been mentioned above.

**PAINFUL LESIONS OF THE MEDIAN NERVE.**—**Causalgia.**—In many cases the most prominent symptom of injury causing an incomplete lesion of the median nerve is pain. It comes on about a month after the injury, at first as tingling or pricking in the finger-tips and palm, later as a constant severe smarting, dragging or burning pain—hence the name causalgia. Added to the constant pain, which never ceases day or night, paroxysms occur, in which the pain increases suddenly in intensity. The application of cold water gives temporary relief, and patients often wear bandages or gloves which they keep constantly moistened. The pain is greatly aggravated by emotional influences.

**Vasomotor changes** are a feature of this type. In many cases perspiration is diminished over the radial half of the palm, and the skin becomes dry and scaly. In others, perspiration is increased over the median area.

**Motor disturbances** are always present, but are usually slight, the weakness affecting mainly the flexors of the index finger and the thenar muscles.

In severe cases the limb is held flexed at the elbow and wrist, with the hand

constantly raised and the fingers extended or hyper-extended. The whole hand atrophies, and irreducible ankylosis occurs with the limb in this position. The skin of the hand is thin and dry. The fingers taper, and the nails are long, brittle, blackened and striated longitudinally. The pain reaches its acme 4 or 5 months after the injury, and then slowly declines, but the limb remains useless. Even in slighter cases, without much deformity, recovery of function is extremely slow, and is rarely complete. The condition is often much improved by early operation and neurolysis of the nerve, or relief may be gained by sympathectomy.

**THE CARPAL TUNNEL SYNDROME.**—The median nerve may be compressed at the wrist as it passes through its tunnel in the transverse carpal ligament. The condition is common in middle life in women engaged in housework, laundrywork and other manual labour, and also at an earlier age in women who have young children. The chief complaint is of pain or numbness in the middle three fingers but frequently discomfort is complained of also in the forearm, and this occurs particularly at night. Pressure at the carpal tunnel is thus one of the causes of acroparæsthesia. In the more severe cases wasting of the upper part of the thenar eminence may be observed and some sensory impairment may be found over the affected fingers. At operation the median nerve is found compressed in its tunnel and swollen for a short distance proximal to its entry into the carpal ligament. Opening up the tunnel relieves the symptoms. In occasional cases some weakness of the fingers results in consequence of the failure of the weakened carpal ligament to retain the flexor tendons in their normal position.

#### THE ULNAR NERVE

This nerve supplies the ulnar flexor of the wrist, the ulnar half of the deep flexor of the fingers, the muscles of the hypothenar eminence, the interossei, the two inner lumbricals and the adductor and inner head of the short flexor of the thumb. Its sensory area is the ulnar border of the hand, the little finger and the inner half of the ring finger.

**TOTAL PARALYSIS.**—Paralysis of the *flexor carpi ulnaris* may be detected by palpating the tendons when the wrists are flexed against resistance. The limpness on the affected side contrasts strongly with the firmness on the sound side. Lateral movements of the hand are unaffected, as these are carried out by the extensors.

Paralysis of the ulnar portion of the *flexor profundus digitorum*. In making a fist, flexion of the index finger is perfect and that of the middle finger good, whilst in the ring and little finger it is absent or very feeble. This weakness is best seen when flexion is attempted with the index and middle fingers extended. Even when the fingers can be flexed by the action of the flexor sublimis, the power of resisting passive extension is completely lost in the terminal phalanx of the two ulnar fingers. Paralysis of the *hypothenar* muscles abolishes lateral movements of the little finger, and diminishes the power of flexion at the proximal joint. Paralysis of the interossei and of the inner two lumbricals leads to the production of the "claw-hand".

The action of these muscles is to flex the fingers at the proximal joints with the distal joints extended. In the "claw-hand" the posture of the fingers is just the opposite of this, namely, extension at the proximal joint with flexion of the distal joints. Although all the interossei are paralysed, the defect is seen only in the ulnar fingers, as the radial lumbricals supplied by the median are still healthy. It is produced by the action of the long extensors, which being now unopposed, over-extend the proximal joints, and by the flexor sublimis which flexes the second joint and draws the distal joint down with it. The clawing of the fingers is greatly accentuated when the nerve is paralysed below the point of origin of the fibres to the long flexors of the fingers. Other features of the "ulnar hand" are atrophy of the interossei and of the hypothenar eminence, and persistent abduction of the little and ring fingers.

The movements of abduction and adduction are lost in the inner two fingers, and often in the middle finger. Further, these fingers cannot be flexed at the distal joint, whilst the proximal joints are extended.

Paralysis of the *adductor pollicis* and of the inner head of the *flexor brevis pollicis* produces peculiar disturbances in prehensile movements. If the patient is asked to grasp a folded paper between his thumb and index finger, and to resist efforts to remove it by pulling, it will be found that this movement, which is normally very powerful, is grossly defective. He cannot grasp the object beneath the thumb with the second phalanx extended; but presses the tip of the flexed thumb against the outer margin of the index finger.

*Sensory disturbances.*—In complete lesions, all forms of sensation are abolished in the little finger, and along the ulnar border of the hand. Beyond this there is usually diminished sensibility on the ulnar side of the ring finger, and over a narrow area towards the centre of the hand on both aspects. Spontaneous pains are rare, and vasomotor changes are usually slight.

*PARTIAL PARALYSIS.*—In partial lesions the same symptoms are found in a less degree. The small muscles of the hand suffer most. Clawing may be slight or absent. Neuralgic pains may be felt in the distribution of the ulnar nerve; but *causalgia* is never seen in lesions of this nerve alone.

*Recovery* of sensation is usually complete before movement is regained. The *flexor carpi ulnaris* recovers first, then the long flexors of the fingers and last the small muscles of the hand. In these recovery is extremely slow. When recovery of movement is complete the patient can abduct and adduct the middle finger with the palm flat on a table, and he can also scratch the table with the nail of the little finger without moving his wrist.

#### THE MUSCULO-CUTANEOUS NERVE

This is rarely affected alone, but is often implicated with the brachial plexus. It supplies the biceps, coraco-brachialis and brachialis. Flexion of the forearm can still be carried out by the *brachio-radialis*; but the power of flexion is greatly diminished. Sensation may be diminished or lost along the radial border of the forearm.

#### THE AXILLARY NERVE

This nerve supplies the deltoid and *teres minor*, and the skin over the deltoid. It may be injured alone in injuries of the shoulder and by pressure of a crutch. The chief symptom is paralysis of the deltoid with almost complete inability to raise the arm.

In war injuries lesions of the nerves of the lower limb are very frequent; but in civil practice, apart from sciatica and foot-drop, local lesions of these nerves are uncommon.

#### THE LUMBO-SACRAL PLEXUS

The *lumbar plexus* may be damaged by abdominal tumours, and its roots by new-growth or other disease of the vertebrae. In a certain number of cases signs of inflammation of the lumbar plexus are found in association with sciatica or neuritis of the *sacral plexus*.

The *sacral plexus* may be damaged by growths or inflammation in the pelvis, by compression during parturition, and by penetrating missiles. It is also often the seat of spontaneous neuritis.

FEMORAL NERVE ( $L_2, L_3, L_4$ )

This is the largest branch of the lumbar plexus. It supplies the iliacus, pectineus, sartorius and quadriceps femoris. It may be injured alone by fractures of the pelvis or of the femur, by dislocations of the hip, or by implication in wounds, psoas abscesses or new-growths.

The most prominent symptoms are loss of power to extend the knee, loss of the knee-jerk, wasting of the quadriceps and sensory disturbances over the anterior surface of the thigh and inner surface of the leg. The psoas always escapes, unless the plexus itself is also damaged; but flexion at the hip may be imperfect through paralysis of the iliacus. Owing to the rapid dispersion of the branches in the thigh, wounds in this part often cause partial lesions. In these the *nerve to the quadriceps* is most often injured. The resulting paralysis causes serious disability in walking as the knee gives way at every step, especially in going down stairs, and lameness lasts for a long time after return of voluntary movement.

OBTURATOR NERVE ( $L_2, L_3, L_4$ )

This nerve is rarely damaged alone. It supplies the three adductor muscles, the obturator externus and the gracilis. The symptoms are weakness of adduction and internal rotation at the hip.

LATERAL FEMORAL CUTANEOUS NERVE ( $L_2, L_3$ )

This nerve supplies an area of skin on the antero-lateral aspect of the thigh. As a result of injury, but more often without obvious cause, the skin in the territory of this nerve may show peculiar sensory disturbances, which have been described under the name of *meralgia parasthetica*. Most cases occur in men. In women it is usually associated with pregnancy. The nerve is tender on pressure at the point where it passes from under Poupert's ligament, and neuralgic pain or numbness and tingling is felt in the skin, which may be slightly insensitive on objective examination or extremely hyperæsthetic, so that the slightest touch causes pain. The symptoms, which are always unilateral, are made worse by walking, and may cause serious incapacity by their persistence and severity. In severe cases the nerve should be excised.

THE SCIATIC NERVE ( $L_4, L_5, S_1, S_2, S_3$ )

This supplies the flexors of the leg and all the muscles below the knee. It may be involved in pelvic new-growths, or injured by fractures of the pelvis or femur. Next to the radial and ulnar it suffers in gunshot wounds more often than any other nerve.

**TOTAL PARALYSIS.**—The foot drops, and the toes point downwards. Walking is possible, but the patient cannot stand on the heel or toes of the paralysed foot. The knee is raised high, but the stepage is not so marked in total lesions as when the common peroneal alone is paralysed. All movement below the knee is abolished. When the wound is in the buttocks, flexion of the knee is very weak. The foot becomes œdematous if allowed to hang down. Sweating is often absent on the sole and dorsum of the foot, but is normal on the inner side of the foot, which is supplied by the femoral. The skin is dry and thin, and may be scaly. Hyperkeratosis of the sole is common. Subjective sensibility is rarely affected. The skin is completely anæsthetic over the entire foot, except the inner border of the sole and around the internal malleolus. The anæsthesia extends upwards on the postero-external aspect of the calf in its lower two-thirds, embracing the tendo Achillis and external malleolus. Beyond this area of complete anæsthesia there is a wide zone in which sensibility is diminished. The sense of position and passive movement is abolished in the foot and toes. The knee-jerk is present. The ankle-jerk is always lost.

**PARTIAL PARALYSIS.**—In wounds of the sciatic nerve it often happens that the fibres of the common peroneal alone are wounded, since the sciatic trunk often divides into the tibial and common peroneal branches as high as the great sciatic notch. The symptoms are described below under paralysis of these nerves. In other cases, the fibres of the tibial nerve are damaged either alone, or with some of the fibres of the common peroneal. In this case the outstanding clinical features are paralysis of the muscles of the calf and foot, anæsthesia of the sole and, with incomplete lesions, pain similar to that described in partial lesions of the median nerve.

#### COMMON PERONEAL NERVE

This nerve may be injured as it winds round the fibula by wounds or fractures or by compression of a tight bandage. The paralysis is usually severe, all the muscles being equally affected. The foot is dropped and inverted, and the toes are slightly flexed. Dorsiflexion of the foot, extension of the proximal phalanges of the toes and abduction of the foot are impossible. The patient can walk, and he can stand on tiptoe, but he cannot run, and walking is made difficult by the foot-drop. Subjective sensory disturbances are usually absent. The skin is anæsthetic over a narrow band which extends from the outer surface of the leg in its middle third, downwards beside the outer border of the tibia, and along the middle of the dorsal aspect of the foot as far as the base of the toes. For an inch or so, on both sides of this band, the sensibility of the skin is diminished. The knee-jerk and ankle-jerk are present. The plantar response is always flexor. Vasomotor changes are slight, and trophic changes are absent.

#### TIBIAL NERVE

This nerve is rarely injured alone. It supplies the popliteus, the calf muscles, the flexors of the toes and the intrinsic muscles of the foot. When it is paralysed, the patient is unable to stand on tiptoe, or to extend or invert the ankle, or to flex his toes. Paralysis of the interossei leads to a claw-like deformity of the foot, associated with lowering of the heel and raising of the metatarsus—talipes calcaneo-valgus. The calf muscles are flabby and the ankle-jerk is abolished. Sensation is lost on the sole, except along its inner border, on the outer border of the foot and on the plantar surface of the toes. Causalgia, similar to that in paralysis of the median, is very often present.

The distal portion of the tibial nerve may be injured by a penetrating missile or a deep wound in the calf. Movements of the ankle are unaffected and anæsthesia is confined to the sole of the foot and heel, or merely to its inner half. The paralysis of the intrinsic muscles of the foot may escape detection, and the lesion may easily be overlooked, especially when the nerve is injured below the origin of branches supplying the flexor longus hallucis and the flexor longus digitorum. The symptoms then are pain in the sole of the foot, anæsthesia on the sole and paralysis of the plantar muscles.

**Treatment of Local Nerve Lesions.**—Treatment must depend on the nature and degree of the lesion. During the long period which elapses between the onset of paralysis and the first signs of recovery, even in cases of simple physiological interruption of the nerves, every effort must be made to prevent degeneration of the muscles, to keep the circulation of the limb active, and to prevent the occurrence of contractures and deformities. Massage, movements, electrotherapy and suitable appliances all have their uses. With regard to operative treatment, it must be remembered that more than half the cases of nerve injuries undergo spontaneous cure. It is advisable, therefore, to wait 3 or 4 months before an operation is undertaken. If, at the end of this time, the wound is soundly healed and all signs of sepsis have

disappeared, and if, as a result of repeated examinations, no sign of recovery has been detected, no harm can be done by exposing the nerve. If it is found to be divided completely, the ends should be "freshened" and sutured end to end. If the nerve is notched laterally, the edges of the notch should be pared and sutured, care being taken to preserve the bridge of uninjured tissue. Sometimes the nerve at the site of the lesion appears as a fibrous, flattened band between two swellings on the nerve. In most of such cases the nerve is completely divided, and the condition calls for resection of this fibrous tissue and end-to-end suture. Another common finding, when the nerve is exposed, is a nodule or cicatricial swelling in the course of a nerve which has maintained its continuity. In these cases the continuity of the nerve should not be interrupted. It should be freed from adhesions, and incised in the long axis of the swelling. Operations which involve grafting of nerves have met with little success. For an account of the advances in the technique of the surgical treatment of nerve injuries which have been made as a result of experience gained in the Wars of 1914-1918 and 1939-1945, special treatises must be consulted.

The treatment of painful forms of nerve lesions is extremely difficult. In severe cases external applications and internal medication entirely fail. Simple freeing of the nerve sometimes gives relief. Where this fails, it may be advisable to practise complete division followed by immediate suture. In other instances sympathectomy, by excision of the stellate ganglion in the case of the upper limb and of two or more of the lumbar sympathetic ganglia in the case of the lower limb, may give lasting relief.

## INTERSTITIAL NEURITIS

**Synonym.**—Neuro-fibrositis.

**Definition.**—A painful malady which commonly attacks the large nerve plexuses or nerve trunks but which may affect any peripheral nerve, and is believed to be due to inflammation of the interstitial connective tissues which surround and bind together the nerve fibres into the nerve trunks.

**Ætiology.**—It is in general a malady of middle life, being unknown in childhood and uncommon in old age. It is often associated with other forms of fibrositis and especially with arthritis, e.g. the brachial nerves being affected in some cases of arthritis of the shoulder and the sciatic nerve in certain cases of arthritis of the hip. Injury involving stretching, bruising or wounding of a nerve trunk may produce it, but it is necessary to bear in mind that pain following an injury, even after a long interval, may be the result of the rupture of an intervertebral disk which has been injured at the same time. Gout, diabetes and chronic nephritis are well known clinical associations of interstitial neuritis.

**Symptoms.**—These are those of irritation of the nerve fibres. Pain is usually the outstanding feature. It radiates in the area of distribution of the affected nerve, *is of a dull, aching character, with acute exacerbations and is often very long-lasting* and wearing to the patient. The affected nerve is tender to pressure and stretching. Subjective peripheral sensations, such as tingling, burning or numbness, are usual and are often the first symptoms. There is marked hypotonus of the muscles of the affected limb, followed by a degree of general wasting, not confined to the muscles supplied by the affected nerve, but resembling arthritic muscular atrophy. Fibrillation sometimes occurs and cramps are common. The deep reflexes of the limb are increased. Trophic and vasomotor changes are not infrequent.

**Diagnosis.**—There is often considerable difficulty in the diagnosis of interstitial neuritis on account of the almost identical clinical picture which may occur in the early stages of pressure upon nerve roots or nerves by tumours, or as a consequence of the irritation of one or more nerve roots by the extruded nucleus of a ruptured

intervertebral disk. The special problems of the sciatic nerve are discussed under the heading of sciatica, but the following points are of value in distinguishing in general between interstitial neuritis and the effects of pressure on nerves. With pressure lesions the pain is rarely so severe as that of interstitial neuritis, tenderness on pressure of the nerve trunks is absent and signs of loss of function—paralysis and sensory loss—come on early. The most careful search should be made in every case for any possible cause of local pressure, such as primary and secondary neoplasms, vertebral and spinal tumours and spinal caries. To make a diagnosis of interstitial neuritis in the presence of a mammary or other carcinoma, or after its removal, is to advocate the highly improbable, whatever the symptoms may be.

**Treatment.**—The details of treatment vary according to the site of the nerve or nerves affected, but the general principles are to secure rest and to avoid all those things which excite or increase the pain. In most cases warmth in all forms has a beneficial and comforting effect; the part should be kept warmly clad, but if special applications, such as radiant heat or infra-red rays, excite pain they should not be persisted with. Salicylates and all the analgesics of the coal-tar series are valuable aids. In the acute stage, morphine preparations may be required to obtain sleep for the patient, but later, combinations of aspirin with barbiturate hypnotics suffice.

### CERVICO-OCCIPITAL NEURITIS

This condition, which is by no means rare, is characterised by pain in the upper part of one side of the neck, radiating over the branches of the upper cervical plexus, the great auricular being the most common, and the supra-sternal, supra-clavicular and supra-acromial branches less common seats for the pain. The fibrositis not infrequently co-involves the fibrous structures in the region of the articular and transverse processes, giving rise to pain and stiffness of the neck on movement. When the pain is confined to the great occipital distribution alcohol injection is sometimes most efficacious.

### BRACHIAL NEURITIS

Two varieties of neuritis affect the brachial plexus and its branches, namely, a paralytic variety and a non-paralytic, the latter being one of the forms of interstitial neuritis.

#### PARALYTIC BRACHIAL NEURITIS

This variety, rare before 1939, has been common in England during recent years, and occurred not infrequently in the armies abroad. The cause of the condition is unknown, but the course of the malady resembles that of an infective disease, and in many cases the onset of the neuritis has occurred while the patients were in hospital suffering from an infectious illness of the respiratory or alimentary system.

**Symptoms.**—Severe pain in the shoulder or side of the neck, radiating down the arm is usually the first symptom, but in a few cases no significant pain occurs. In the more severe cases general malaise accompanies the onset. After a few days paralysis is noticed, affecting, as a rule, some of the more proximal muscles innervated from the brachial plexus. Paralysis of the serratus anterior, with consequent winging of the scapula, is especially frequent, and if the patient is in bed because of other symptoms, this disability may escape notice until he is up and about again, and begins to use the arm of the affected side. If the paralysis affects the muscles of the upper arm, wasting is soon evident. All the tendon-jerks of the affected arm or of both

arms may be abolished. Tenderness is present over the brachial plexus and may persist for several weeks. Sensory loss is, as a rule, slight or absent. The cerebrospinal fluid is usually normal.

**Differential Diagnosis.**—This malady, as a rule, only requires to be known about to be recognised, but in subjects of military age or younger the diagnosis has to be made from poliomyelitis. In the latter, the onset is more abrupt and in adults is accompanied by a greater degree of malaise and fever, stiffness of the neck is usual and Kernig's sign may be present; the cerebrospinal fluid contains a considerable excess of lymphocytes, followed by a gradual rise of protein during the weeks succeeding the onset of the paralysis. The paralysis tends to have a segmental distribution, whereas in the case of brachial neuritis it has much more tendency to be limited to the muscles supplied by one or two individual nerves.

**Course and Prognosis.**—In this variety of brachial neuritis the pain usually passes off within a few days and sensory loss, if any, is soon recovered from, but the outlook as regards recovery of the muscular paralysis is always doubtful, and if such occurs, it takes many months.

**Treatment.**—The cause of the disease being unknown, treatment can only be on general principles. Analgesics are given for the relief of pain, and the affected limb is supported in such a position as to relax the paralysed muscles. Preparations of vitamin B are often exhibited, but it is doubtful whether they are of any value in aiding the recovery of the affected nerves in this disease.

#### INTERSTITIAL BRACHIAL NEURITIS

**Ætiology.**—This variety of brachial neuritis is somewhat uncommon, and is met with chiefly in patients over the age of 40. It often arises spontaneously, but is frequently associated with arthritis in the shoulder or neck, and it may follow injury to the brachial plexus from any violence causing undue separation of the head and the shoulder.

**Symptoms.**—Brachial neuritis of this variety has the general characters of interstitial neuritis. The pain, which is often of abrupt onset, may be of great severity and may be at first referred to the region of the plexus itself, the back of the scapula, the axilla, the forearm or the hand. Whatever its site, the pain is at first intermittent, but it soon becomes continuous and spreads over the whole upper limb. Tingling and numbness in the hand, and trophic changes in the skin and finger-nails are the rule. With minimal degrees of this form of brachial neuritis, tingling in the hand in the morning is a common symptom.

**Diagnosis.**—It may be impossible to make the diagnosis from brachial pain due to protrusion of one of the intervertebral disks in the lower cervical region (*vide infra*). Other conditions likely to cause confusion are arthritis of the shoulder and cervical rib, but in neither of these conditions is there tenderness of the nerve trunks or of the plexus.

**Treatment.**—One of the great difficulties in this malady is that in the upright position the weight of the arm and shoulder carries the latter downwards, and so stretches the inflamed plexus, adding greatly to the pain. The patient, therefore, should be kept in bed and in general on his back. Further, every movement of the hand or arm tends to increase the pain, and splints which keep the arm in the abducted position and the shoulder raised so as to prevent tension upon the plexus are invaluable.

#### BRACHIAL PAIN DUE TO A PROTRUDING INTERVERTEBRAL DISK

In a considerable number of cases brachial pain which would in the past have been diagnosed with confidence as due to brachial neuritis is, in fact, the result of irritation of one or more cervical nerve roots by a displaced intervertebral disk.

In such cases the onset of pain is usually sudden, and often follows forceful movement of the neck or prolonged strain on the cervical muscles with the head partially rotated, as may occur in supporting a heavy weight.

The pain is usually described as being intense in severity, and is felt across the base of the neck and between the shoulder blades, and is usually worse on one side. It is aggravated by movement or jarring of the neck or by straining.

After a few days the cervical pain usually abates somewhat in severity but pain extends down the arm to the digits on one or other side of the hand.

When examined, the patient is found to have considerable limitation of movement of the neck, and may show severe signs of a radicular lesion in the arm in the form of muscular wasting or weakness, sensory impairment and diminished reflexes. The root most commonly affected is the sixth cervical and the patient's chief complaint is of pain in the arm and pain, tingling and numbness in the index finger and to a less degree in the thumb; on examination some sensory impairment is found over the index finger and the triceps jerk is diminished or lost, and, after a time, some diminution of the muscles of the forearm is apparent on comparison with the normal limb.

Such cases usually recover gradually with symptomatic treatment but some stiffness of the neck may remain. Recovery can often be greatly accelerated by manipulation of the neck combined with axial traction, which should only be carried out by an expert in manipulative methods.

## CERVICAL RIBS

**Ætiology.**—The development of the ribs at the thoracic inlet depends on the mode of formation of the brachial plexus, for the nerves are large structures in the embryo at a time when the ribs are soft and pliable. When the plexus is "normal", a well-formed first rib springs from the first dorsal vertebra. If, however, the plexus is "post-fixed", that is, when the contribution to the plexus from the fourth and fifth cervical segments is small and the fibres from the first and second dorsal segments form a powerful cord, this cord in rising over the first dorsal rib may compress and deform it to such an extent that it presents the characters of a rudimentary rib. On the other hand, and this is more frequent, when the plexus is pre-fixed, that is, when the contribution from the upper cervical segments is relatively large and that from the dorsal segments is small, a supernumerary rib is allowed to develop from the seventh cervical vertebra. When this pre-fixation is pronounced, the seventh cervical rib is often very large and is easily felt in the neck, and in these cases symptoms are usually absent. In a certain number of cases in which the abnormality is intermediate in degree, symptoms are caused by compression of the lower cord of the plexus as it passes over the supernumerary rib, or over the deformed first rib. This compression may be exercised by the bony portion of the extra rib, but more often the nerves are damaged by a fibrous prolongation of the rudimentary rib which connects it with the first rib.

But these abnormalities in the ribs only cause symptoms in some 10 per cent. of the cases in which they are present. Further, the symptoms are often unilateral with bilateral supernumerary ribs, and the symptoms are often most prominent on the side of the smaller extra rib. Again, the onset of symptoms is usually delayed until adult life is reached. It is clear, therefore, that some contributory cause must come into play. This is found in the dropping of the shoulder girdle, which is normal in adolescents, and is often excessive in persons whose muscular tone is low. In a child the clavicle rises boldly as it passes outwards. In a normal adult male the clavicle is almost horizontal, in women it droops slightly, and in those who develop symptoms of pressure on the nerves, the outer is usually distinctly lower than the inner end.

In the latter, the lowest cord of the plexus is submitted to constant rubbing against the extra rib which rises and falls during respiration, and it is compressed by any movement of the arm which depresses the shoulder girdle. Relief is obtained by raising the shoulders, and patients soon learn to support the limb and to assume attitudes in which pressure on the nerves is relieved.

Women suffer most often, the right arm being affected more often than the left. The onset is usually gradual, but occasionally it comes on suddenly after childbirth, or on lifting a heavy weight.

**Symptoms.**—These may be sensory, motor or vasomotor, either singly or in combination. Subjective sensory disturbances are most frequent. They take the form of numbness and tingling or neuralgic pains. Paræsthesiæ are most often unilateral, and are frequently confined to the ulnar or to the radial side of the hand and fingers. It is rare for all the fingers to be affected. Pain, when present, is usually felt below the elbow. It is often neuralgic, darting down the arm and again confining itself to one border of the limb. It hardly ever radiates from the neck.

Objective sensory disturbances are usually slight or absent. They may be found over the ulnar or radial border of the distal portion of the limb in an indefinite area, which does not conform to the distribution either of the ulnar or radial nerve.

Muscular atrophy is not so frequent as subjective sensory disturbance. In the "median type", wasting is confined at first to the abductor and opponens pollicis muscles, and the outer part of the thenar eminence shows a remarkable reduction in size, which contrasts strongly with the inner part, which retains its normal bulk. In the "ulnar type", wasting appears first in the small muscles of the hand supplied by the ulnar nerve. In some cases all the muscles of the hand and, to a less degree, the flexors in the forearm show considerable wasting. The atrophy is frequently bilateral and symmetrical.

Vasomotor disturbances are very common. The hands feel hot or cold, they may be œdematous or discoloured and the changes may suggest Raynaud's disease. Pressure on the subclavian artery sometimes causes inequality of the pulse, and the pulse on the affected side may be obliterated by depression of the shoulder. The inequality disappears when the arm is raised.

**Diagnosis.**—The presence of pain, paræsthesiæ or vasomotor disturbances in the upper limbs, or wasting in the muscles of the hands, should always arouse the suspicion of supernumerary or rudimentary ribs. When pain is the only symptom, its distribution along one border of the arm or hand, and the patient's account of the manner in which it may be increased or diminished by raising the shoulder girdle or performing movements which depress it, usually direct attention to the cause. Symmetrical atrophy in the hands may suggest progressive muscular atrophy of spinal origin, but this diagnosis is usually rendered untenable by the association of sensory troubles or vasomotor phenomena, or by the findings on radiographic examination of the neck. For the differential diagnosis from syringomyelia, see p. 1547. Symptoms indistinguishable from those which commonly result from the presence of a cervical rib occur in a small number of patients in whom no cervical rib is present. In most cases of this kind, the patients have very sloping shoulders, and the symptoms are believed to be due to compression of the roots of the brachial plexus between the fibre-bundles of the scalenus anterior muscle. In other cases, either because of the lowness of the clavicle or because the first rib is unduly high, the subclavian artery is compressed between these two bones, when the corresponding arm hangs down or when it is raised and abducted. Obliteration of the circulation causes a numbness in the hand and forearm, which comes and goes according to the posture of the arm. The numbness may become persistent because of thrombosis at the site of compression, and the patient may first come for advice when this has occurred. Aneurysm is another occasional consequence of the damage to the artery.

**Treatment.**—Pain may be relieved by rest with the arms suitably supported.

Atrophy calls for operation to remove the offending rib. Pain is always relieved by operation, either immediately or after an interval of some months. The progress of atrophy is always retarded, and complete recovery may occur if an operation is undertaken early.

### ACROPARÆSTHESIA

**Definition.**—Acroparæsthesia is the name given to a syndrome of uncomfortable tingling in the extremities without demonstrable sensory loss or other abnormal physical signs.

**Ætiology.**—It is unusual for all four limbs to be affected; acroparæsthesia in the arms is much commoner than that in the legs. In the arms it is almost limited to women, whereas in the legs it is much commoner in men. There seems to be an hereditary element in its causation. As first described it was associated with arthritis and it seems to be commoner in arthritic subjects, but both maladies occur in the same age group. In both sexes the condition usually comes on in middle life, but it also occurs in younger women during pregnancy.

**Symptoms.**—The tingling may be present at all times, but it occurs above all during the night and wakens the sufferer from sleep; some patients complain of the inability to sleep as much as of the discomfort. The tingling is in some way due to the use of the limbs during the day in vigorous work, or in continuous standing or car-driving, and if the patient rests throughout the day he or she is, as a rule, soon relieved of his nocturnal symptoms. Many of the patients are middle-aged women who have been compelled to do vigorous housework to which they have not been accustomed from youth. In general, warmth aggravates the tingling and the sufferer who is awakened in the night puts the affected limbs outside the bedclothes. In the less severe cases the symptoms are worst during the early part of the night and after a number of hours of broken sleep the patient is able to sleep without interruption for the rest of the night. In other cases the symptoms continue throughout the night and are still present in the morning; then the hands may appear, or may feel, swollen, and the patients complain of awkwardness of the fingers, but impairment of postural or other sensation can rarely be demonstrated.

The symptoms are subject to long remissions, but the liability to them is not often completely lost.

**Diagnosis.**—There are no objective signs of nervous or vascular disease. The most careful examination must be made to exclude such causes of paræsthesiæ as sub-acute combined degeneration and early polyneuritis (e.g. diabetic or lead). If the tingling is limited to a part of the hand it may be due to compression of the median nerve in the carpal tunnel, or to disturbance of the ulnar nerve, or to compression of a nerve root by an intervertebral disk. Slight wasting of muscles may give a clue to the presence of some organic disease. The state of the pulses in the affected limbs may suggest the presence of a vascular disturbance to which the symptoms are attributable.

**Treatment.**—As has been stated, the tingling, as a rule, ceases if the patient does no work, but social circumstances rarely make continued leisure possible; the patient may, however, be able to find more suitable employment or to make changes in his or her habits of work, or a holiday, particularly with sea-bathing, may initiate a remission. Sponging the affected limbs with cool water once or twice in the day and possibly at night gives considerable relief in most cases. The combination of aspirin gr. 10 with phenobarbitone or other hypnotic, taken at bedtime, enables the patient to sleep.

### SCIATICA

The term "sciatica" is applied in a somewhat imprecise manner to conditions in which pain is experienced along the course and in the distribution of the sciatic

nerve—that is to say, in the buttock, back of the thigh, outer side and back of the leg and the outer border of the foot. It is important at the outset to notice the limitations of this distribution and, in particular, to notice that the sciatic nerve does not supply any structures on the front of the thigh, and so pain in that region or in the groin is not included in sciatica.

Cases of sciatica as thus defined are common, and many of them have a prolonged course and other well-described features. Until recent years they were all confidently attributed to interstitial neuritis (sciatic neuritis) but it is now recognised that, while a number are probably due to this cause, many are the result of irritation of one of the roots of the great sciatic nerve by the extruded nucleus of a ruptured intervertebral disk, and others are cases of referred pain in the sciatic distribution. The differential diagnosis between these different varieties of sciatica is frequently a matter of great difficulty, and in fact in many cases it cannot as yet be made with confidence.

#### SCIATICA DUE TO PROTRUDING INTERVERTEBRAL DISK

Sciatica is the syndrome to which herniation of the nucleus pulposus of a lumbar intervertebral disk most commonly gives rise.

**Ætiology.**—The majority of cases give a history of injury at, or shortly before, the onset of symptoms. The injury is commonly of the variety known as a strain of the back, due to sudden bending, the lifting of heavy weights or sudden movements of the back, as when striving to avoid a fall. Males are more commonly affected. In females, childbirth, especially with instrumental delivery, is an additional cause.

**Pathology.**—Formerly the condition under discussion was one recognised on laminectomy, and spoken of as endochondroma of the disk. Actually in the circumstances enumerated above, the disk ruptures and its nucleus (nucleus pulposus) subsequently herniates into the vertebral canal. The commonest site of such a lesion is in the lumbar spine, below the termination of the spinal cord, and the extruded mass causes irritation and compression of one or more of the roots of the cauda equina. The disk most frequently ruptured is that between the fifth lumbar vertebra and the sacrum (fifth lumbar disk), and the spinal root affected is the first sacral. The fourth lumbar disk is also commonly ruptured and the third lumbar occasionally so. The rupture of higher lumbar intervertebral disks is infrequent. In each case the spinal root most affected is that emerging just below the site of the lesion, *e.g.* the fifth lumbar root when the fourth lumbar disk is ruptured and so on. Multiple ruptures are not very uncommon.

**Symptoms.**—The outstanding feature is pain. It begins in the small of the back either at the time of the injury or after an interval of some hours, days or weeks. It may remain limited to the back, but in most cases it extends, after a variable interval, down the back of one thigh, and then down into the leg and possibly into the foot, so that the clinical condition becomes one of “sciatica”. The exact distribution of the pain in the leg depends on which spinal root is affected (*vide infra*). The pain is severe and lancinating, aggravated by stooping, by coughing and sneezing, and by turning in bed, and relieved by lying still. Flexion of the extended leg at the hip is always painful (Lesègue’s sign), and the patient adopts an attitude of partial flexion of the affected limb at the knee and hip, which avoids tension on the sciatic nerve and its roots.

The objective physical signs fall into two groups, namely, (1) those referable to the spine, and (2) those due to impairment of function in the affected nerve-root or roots. The lumbar spine is flattened and is tilted at the site of the lesion; the tilt is usually away from the side of the sciatic pain but may be towards it and in some cases the tilt alternates. Radiographic examination reveals the flattening of the lumbar curve and the tilting more clearly, and it may show a suggestive reduction of one intervertebral space but this is not usual. The nervous signs are in general those

of impairment of function of a single spinal root. Most commonly the first sacral root is the one involved, and the signs which develop are as follows: The ankle-jerk is abolished. The muscles of the calf and the peronei become slightly wasted, and the change in outline is apparent when the two legs are compared with the patient standing up or lying prone. The power of flexion of the small toes is diminished. The glutei on the affected side are flattened. Sensation is impaired along the outer border of the foot and on the outer half of the sole, and the patient has a sensation of numbness or tingling in this area. The impairment of sensation may be a loss or weakening of pain appreciation, and loss of tickle on the affected area of the sole, or a loss of light touch appreciation, or a loss of sense of position of the small toe, or all of these combined. When the fourth lumbar disk is ruptured and the fifth lumbar root is consequently most affected, the site of the worst pain is on the outer side of the leg and perhaps on the dorsum of the foot, wasting of the calf is less pronounced, and the ankle-jerk is more often diminished than abolished; an area of sensory loss for light touch or impairment of pin-prick appreciation may be found on the outer side of the calf. In severe cases some disturbances may be found in the functions of the first sacral root as well as in those of the fifth lumbar. With lesions of the higher lumbar disks the pain is maximal in the fourth or higher root distributions, and the knee-jerk may be diminished or lost.

It should be borne in mind that in a proportion of cases the nervous symptoms are entirely irritative, and consequently objective signs due to impaired root function are lacking. Spinal signs are usually present, and ultimately some wasting appears, but in a number of such cases it is as yet impossible to make the differential diagnosis from sciatic pain due to other causes.

**Diagnosis.**—When the diagnosis is in doubt special radiographic examination after injection of Myodil into the theca shows a filling defect in the Myodil shadow, corresponding to the knuckle of cartilage indenting the theca. This method of investigation is not infallible, but in the present state of our knowledge its results should be taken as a practical guide.

In almost every case the problem is to distinguish the symptoms of a ruptured intervertebral disk from "sciatica" due to other causes. Most cases of sciatica in people under 40 years of age are due to ruptured discs. As age increases, other causes assert themselves more strongly, but in people who are of athletic type, given to such forms of physical activity as gardening, horse-riding and golf, and who are free from arthritis, ruptured disk is always a likely cause. If there is some history of injury or strain, if both the spinal and nervous groups of signs are present, and if the latter are limited to the distribution of a single root, there is little doubt about the diagnosis. In cases of sciatic neuritis, tenderness along the line of the sciatic trunk is pronounced, and pain and tenderness are seldom limited to the distribution of a single spinal root. In cases of referred sciatic pain, reflex changes, muscular wasting and objective sensory loss are absent. Very prolonged and, especially, recurrent sciaticas are mostly due to ruptured intervertebral disks.

**Course and Prognosis.**—In the absence of operative treatment, the symptoms usually subside gradually in the course of from 6 weeks to 6 months. In a very few cases they clear up more quickly, and in quite a number they persist in some degree for years, sometimes better and sometimes worse. The muscular wasting, though obvious, never becomes severe and there is never total paralysis of the affected nerve-root.

**Treatment.**—It is not known how the structures within the vertebral canal adapt themselves but in most instances the pain subsides without operative removal of the protruding mass. It is to be presumed that the affected nerve root suffers the minimum of physical irritation when the patient takes up the posture which is for him least painful. In general, the patient should remain at rest in his most comfortable position and be given such pain-relievers of the nature of aspirin, veganin and

the like, as may be necessary, together with sedatives if called for. In the most acute cases an injection of morphine, gr.  $\frac{1}{4}$ , or pethidine, 100 mg., may be necessary at night, but both these drugs should be used with great care because of the danger of addiction. Physiotherapy may be comforting after the acute phase has passed, but it is doubtful whether it has any curative effect. When the patient has been free from pain for a week, while still in bed, he may be allowed to sit up and very gradually begin to move about, but he should avoid doing anything which causes pain and he should rest when pain begins. If pain is recurrent when the patient has begun to move about, support of the lumbar spine by a plaster jacket may give relief.

Operation for the removal of the protruding portion of disc is advisable (1) if after 6 weeks or so the pain is not definitely diminished, (2) if the sciatica is recurrent, (3) if the patient's employment involves heavy work and much movement of the back. The operation is not a severe ordeal and most patients are walking again within 3 weeks. In general the results are excellent, but in some cases some pain persists or returns.

### REFERRED SCIATIC PAIN

In some cases of sciatic pain there are no manifestations of disease of the sciatic nerve itself, either in the way of impaired function or of tenderness, and the pain is believed to be a referred pain excited by disease of other structures within the nerve distribution of the spinal segments from which the sciatic nerve arises. Such pain is abolished by the cure of the primary disease or anæsthetisation of the structure which it affects. Conditions which may give rise to referred sciatic pain are arthritis in the hip joint, arthritis in the sacro-iliac joint, disease of the lower lumbar vertebrae or of the sacrum, trauma of the gluteal muscles and lesions of the vertebral ligaments. It should be noted that malignant disease of the lower vertebral bones may cause severe referred sciatica at a time when no bony change is revealed by radiography, and the occurrence of sciatic pain in a patient who has suffered from carcinoma is to be interpreted in the light of this knowledge. Elliott and Weddell have shown that the presence of so-called rheumatic nodules in the gluteal muscles is not to be regarded as evidence of fibrositis there which might excite sciatic pain, because the nodules are due to local muscular spasm consequent upon irritation of nerve fibres, and are not primarily a rheumatic manifestation.

Referred sciatic pain is usually moderate in intensity. Its distribution is usually in the calf or on the outer side of the leg, or on the outer side of the ankle. The calf muscles are slightly tender and are the seat of discomfort, which causes the patient to make movement of them at frequent intervals. The absence of all signs of impaired nervous function has already been mentioned, and is the most important diagnostic feature.

In all cases of referred sciatic pain the treatment is that of the exciting condition. Injection of a local anæsthetic into the disordered structure abolishes the pain temporarily, and occasionally the relief is permanent, especially if the anæsthetic is used in oily solution, the effect of which is more lasting than that of an aqueous solution.

### OBSTETRICAL PARALYSIS

It is important and useful to group together under this heading all those conditions of paralysis occurring, either in mother or child, which are the result of the processes of labour in the passage of the fetal head through the pelvis. Autopsies upon the still-born, and upon children who have survived birth for a few days only, have shown that hæmorrhage into the meninges is of common occurrence, and it has been argued that such meningeal hæmorrhages are the cause of many of the conditions of cerebral paralysis which are present immediately after birth, or which appear during the first

year of life, and especially the cause of cerebral diplegia. The pathological conditions found in the brain in cases of cerebral diplegia, however, are such as make it impossible that they could be caused by meningeal hæmorrhage, for no sign of old hæmorrhage is ever found, nor could hæmorrhage cause a general cell atrophy of the brain without signs of any local lesion. It seems clear, then, that though meningeal hæmorrhage may be of common occurrence during birth, and may be the cause of still-birth, yet there is no clinical or pathological evidence to show that it gives rise to any lasting cerebral defect.

The following conditions may occur: (1) In the child: facial paralysis; hemiplegia from laceration of the brain substance; fracture-dislocation of the spine with transverse lesion of the spinal cord; injury to the brachial plexus from the separation of head and shoulder in traction; and injury to peripheral nerve trunks at the elbow, axilla or groin, in using traction with the finger.

(2) In the mother: paralysis of the supply of the lumbo-sacral cord and obturator nerve from prolonged pressure of the head against the sacrum and pelvis.

*Facial paralysis.*—This is usually caused by the pressure of the forceps upon the facial nerve as it crosses the ramus of the jaw, but it has been known to occur where instruments have not been used. When unilateral, as is the common event, it gives rise to little or no difficulty with sucking, and is evidenced by the unsightly deformity of the face, which is drawn over to the sound side. When bilateral, it is one of the causes of complete inability to suck, and on account of the flaccid symmetry of the face may easily be overlooked. It necessitates spoon feeding for a considerable time. Obstetrical facial paralysis invariably recovers within a few weeks and does not give rise to after-contraction. Gentle stretching and massage of the face with the finger is the only treatment required.

*Hemiplegia* from laceration of the brain may occur during delivery in contracted pelvis from the pressure upon the sacral promontory, and has been caused by the use of forceps. It is exceedingly rare, and is generally rapidly fatal from the associated hæmorrhage. It may occasionally be survived, with an irreparable hemiplegic condition.

Fracture-dislocation of the spine is produced by traction upon the aftercoming head by pulling upon the trunk, and it may be associated with injury to the brachial plexus. It occurs most often in the lower cervical region, and the transverse lesion of the spinal cord is usually complete.

Injury to the brachial plexus may occur in traction either upon the head, or upon the trunk, if the head is aftercoming, and is caused by an undue separation of head and shoulder on one side rupturing or straining the brachial plexus. The paralysis is usually of the upper arm or Erb type, the fifth and sixth roots being most affected, and the deltoid, biceps and supinator longus muscles being paralysed, but the whole plexus may be involved and even torn completely across. Traction upon a prolapsed arm has caused lower arm or Klumpke type of paralysis, in which the first dorsal and eighth cervical roots are most affected, and the intrinsic hand muscles and the flexors of the forearm are paralysed. The obstetrical lesions of the brachial plexus are for the most part serious lesions, many of the cases making no motor recovery at all, though sensibility is usually regained. The prognosis depends upon the severity of the damage to the plexus, as to whether the roots are actually torn or only bruised. The slight cases recover well enough.

Injury to the peripheral nerves from pressure or traction upon the flexures is seldom severe enough to prevent a rapid and complete recovery.

Paralysis of the lumbo-sacral cord and of the obturator nerves in the mother, immediately after parturition, is an exceedingly interesting clinical condition. In the first place, the lumbo-sacral cord is in a much more exposed position as regards the foetal head engaging the pelvis than are the other nerves of the sacral plexus, and may be subjected to such severe pressure as causes paralysis, and in the second place,

the obturator nerve actually crosses the brim of the pelvis and must of necessity be pressed upon by any large fetal head which passes the pelvic brim. The lumbosacral cord paralysis is evidenced by dropped foot and paralysis of the anterior tibial and peroneal muscles and if it is severe, by loss of sensibility over the distribution of the fourth and fifth lumbar roots. Sometimes the third lumbar root area is affected. The obturator nerve involvement is shown by weakness or paralysis of the muscles supplied by the obturator nerve, namely, all the adductor muscles of the thigh. The paralysis may be noticed directly after parturition, or when the patient begins to get about upon her legs. The lumbosacral paralysis is usually unilateral, and is nearly always upon the right side. The obturator paralysis is not uncommonly bilateral, and both forms of the paralysis may coexist. There may be numbness, but no pain. This condition nearly always occurs with a first delivery, and often the child's head has been unduly large. It may recur with subsequent deliveries, but this is not a common event.

The prognosis is absolutely favourable, every case making a complete recovery in from a few weeks to a few months. The treatment is rest in the first place, with gentle massage and passive movements, and when power begins to return the patient may commence to get about.

## POLYNEURITIS

**Synonym.**—Multiple Peripheral Neuritis.

**Introduction.**—The clinico-pathological condition known as polyneuritis, and seen in its most typical form in diphtheritic paralysis, or in alcoholic neuritis, represents a very striking and uniform reaction of the nervous system. Invariably associated with it is a reaction of the myocardium, so that there is in cases of polyneuritis a recognised liability to sudden fatal heart failure. It is in diphtheritic paralysis and beriberi, another form of polyneuritis, that this mode of fatal termination is most often seen. Indeed, beriberi may appear as a rapidly fatal cardiac illness before any signs of involvement of the nervous system have had time to develop.

**Ætiology.**—At first sight the factors that give rise to polyneuritis fall into three groups: (i) certain chemical poisons, (ii) the toxins of certain bacteria and (iii) certain disorders of metabolism. Widely differing as these three causative factors may seem to be, there is reason to believe that a common underlying factor which is immediately responsible for polyneuritis may underlie them all. It is probable that in the case of groups (i) and (ii) the pathogenic substance gives rise to a disorder of metabolism in the course of which a toxic metabolite is produced in the body, this acting as the direct poison for nervous system and heart muscle. In the metabolic group (iii) the same process is in action. Thus, in beriberi, for example, the illness ensues upon the ingestion of a diet deficient in vitamin B<sub>1</sub>. In the absence of this substance carbohydrate metabolism is disordered and a toxic metabolite is produced. Thus, beriberi is not, as the biochemists formerly insisted, a starvation-degeneration of the nervous system, but an intoxication strictly comparable with that obtaining in other varieties, ætiologically considered, of polyneuritis. The final and complete proof of this unity of causation of polyneuritis, in whatever circumstances it is seen, is not yet available, but there is an increasing body of evidence in favour of it.

Returning to the ordinary ætiological classifications of polyneuritis, we see that in alcoholic or arsenical polyneuritis the poison is taken by the mouth, and presumably the final common toxic substance reaches the nervous system by the bloodstream. In diphtheritic paralysis, on the other hand, the exotoxins are produced focally at the site of the diphtheritic ulceration, whether on the fauces, or, as in extra-laricial diphtheria, at some other local site on the body surface. This unique channel of entry gives rise in diphtheritic paralysis to a group of symptoms not found in other

ætiological varieties of polyneuritis. This group includes palatal and accommodation paralyses, which precede the appearance of polyneuritis. It is noteworthy that in the case of extrafaucial diphtheria this initial paralysis is not palatal, but is anatomically related to the site of the diphtheritic lesion (skin ulceration or wound). Yet the paralysis of accommodation may occur whatever be the site of the diphtheritic lesion. It is believed, therefore, that the exotoxins gain access to the nervous system by conduction from the seat of the lesion via the axones of the nerves which innervate this region. They pass upwards in the axis cylinders to the central nervous system and produce their toxic action directly there, this action being reflected peripherally again as a motor and sensory paralysis of the muscles and skin (or mucosa) in the region of the lesion. Thus a diphtheritic ulcer on a finger may be followed by a local paralysis of that part before polyneuritis develops. The subsequently developing polyneuritis is then probably produced in the manner described above, while the accommodation paralysis may indicate a specific action of the toxin upon the nervous mechanism concerned. We thus have a local, a specific and a general group of symptoms. The analogy of the local, specific and general phases of tetanus will occur to the reader.

A peculiar effect of abnormal metabolism is the occurrence of polyneuritis in association with bronchial carcinoma.

Acute febrile polyneuritis and Landry's paralysis have no known causal factors. They make their appearance in apparently healthy persons, adequately nourished and free from all discoverable signs of infection, and it is extremely difficult in the present state of knowledge to account for them on any hypothesis of avitaminosis, or to suggest any possible mode of intoxication.

Many of the intoxications of the nervous system commonly included under the heading of polyneuritis are associated with lesions and clinical manifestations which are not those of polyneuritis. Such substances, to name but a few, are lead, mercury, copper, carbon disulphide and carbon monoxide, and it would be erroneous to regard these as causes of polyneuritis.

**Pathology.**—The changes in the nerves are those of parenchymatous neuritis, and longitudinal sections stained by the Marchi or Weigert-Pal methods show severe degeneration of the fibres. The alterations are most intense in the small branches supplying the skin and muscles, and they diminish in severity as the larger branches are approached. They are best seen in the terminal branches of the musculo-spiral and anterior tibial nerves. The wasted muscles often show a reduction in the size of their fibres, and an increase of connective tissue—fibrous myositis. The spinal cord may be healthy, but in almost all cases examination by modern methods shows changes in the nerve cells and degeneration in the tract fibres derived from the posterior roots.

**Symptoms.**—As might be expected from the composition of the peripheral nerves, the symptoms of polyneuritis may consist of disorders of movement, sensation and autonomic function, and these disorders are symmetrical and typically begin in the peripheral portions of the limbs and spread proximally. The relative severity of these disturbances varies from one variety of polyneuritis to another, and the detailed symptomatology of each variety is more fully considered below. The motor disorder is in all instances a lower motor neurone paralysis, with the characteristic weakness, reflex loss and tendency to wasting of the muscles: a marked propensity to contracture is universal. Bilateral drop foot is in a large number of cases the first objective motor manifestation. The sensory disorders are similarly peripheral and symmetrical and may involve both superficial and deep sensibility and may be both positive (pains and paræsthesiæ) and negative (anæsthesiæ). The first complaint is usually of numbness in the feet and in the hands, and this extends proximally, and is soon accompanied by objective sensory loss, which by reason of its mode of development soon has characteristically a "glove and stocking" distribution. In some varieties the autonomic

the obturator nerve actually crosses the brim of the pelvis and must of necessity be pressed upon by any large foetal head which passes the pelvic brim. The lumbosacral cord paralysis is evidenced by dropped foot and paralysis of the anterior tibial and peroneal muscles and if it is severe, by loss of sensibility over the distribution of the fourth and fifth lumbar roots. Sometimes the third lumbar root area is affected. The obturator nerve involvement is shown by weakness or paralysis of the muscles supplied by the obturator nerve, namely, all the adductor muscles of the thigh. The paralysis may be noticed directly after parturition, or when the patient begins to get about upon her legs. The lumbosacral paralysis is usually unilateral, and is nearly always upon the right side. The obturator paralysis is not uncommonly bilateral, and both forms of the paralysis may coexist. There may be numbness, but no pain. This condition nearly always occurs with a first delivery, and often the child's head has been unduly large. It may recur with subsequent deliveries, but this is not a common event.

The prognosis is absolutely favourable, every case making a complete recovery in from a few weeks to a few months. The treatment is rest in the first place, with gentle massage and passive movements, and when power begins to return the patient may commence to get about.

Thus, beriberi is not, as the biochemists formerly insisted, a starvation-degeneration of the nervous system, but an intoxication strictly comparable with that obtaining in other varieties, ætiologically considered, of polyneuritis. The final and complete proof of this unity of causation of polyneuritis, in whatever circumstances it is seen, is not yet available, but there is an increasing body of evidence in favour of it.

Returning to the ordinary ætiological classifications of polyneuritis, we see that in alcoholic or arsenical polyneuritis the poison is taken by the mouth, and presumably the final common toxic substance reaches the nervous system by the bloodstream. In diphtheritic paralysis, on the other hand, the exotoxins are produced focally at the site of the diphtheritic ulceration, whether on the fauces, or, as in extralaucial diphtheria, at some other local site on the body surface. This unique channel of entry gives rise in diphtheritic paralysis to a group of symptoms not found in other

ætiological varieties of polyneuritis. This group includes palatal and accommodation paralyses, which precede the appearance of polyneuritis. It is noteworthy that in the case of extrafacial diphtheria this initial paralysis is not palatal, but is anatomically related to the site of the diphtheritic lesion (skin ulceration or wound). Yet the paralysis of accommodation may occur whatever be the site of the diphtheritic lesion. It is believed, therefore, that the exotoxins gain access to the nervous system by conduction from the seat of the lesion via the axones of the nerves which innervate this region. They pass upwards in the axis cylinders to the central nervous system and produce their toxic action directly there, this action being reflected peripherally again as a motor and sensory paralysis of the muscles and skin (or mucosa) in the region of the lesion. Thus a diphtheritic ulcer on a finger may be followed by a local paralysis of that part before polyneuritis develops. The subsequently developing polyneuritis is then probably produced in the manner described above, while the accommodation paralysis may indicate a specific action of the toxin upon the nervous mechanism concerned. We thus have a local, a specific and a general group of symptoms. The analogy of the local, specific and general phases of tetanus will occur to the reader.

A peculiar effect of abnormal metabolism is the occurrence of polyneuritis in association with bronchial carcinoma.

Acute febrile polyneuritis and Landry's paralysis have no known causal factors. They make their appearance in apparently healthy persons, adequately nourished and free from all discoverable signs of infection, and it is extremely difficult in the present state of knowledge to account for them on any hypothesis of avitaminosis, or to suggest any possible mode of intoxication.

Many of the intoxications of the nervous system commonly included under the heading of polyneuritis are associated with lesions and clinical manifestations which are not those of polyneuritis. Such substances, to name but a few, are lead, mercury, copper, carbon disulphide and carbon monoxide, and it would be erroneous to regard these as causes of polyneuritis.

**Pathology.**—The changes in the nerves are those of parenchymatous neuritis, and longitudinal sections stained by the Marchi or Weigert-Pal methods show severe degeneration of the fibres. The alterations are most intense in the small branches supplying the skin and muscles, and they diminish in severity as the larger branches are approached. They are best seen in the terminal branches of the musculo-spiral and anterior tibial nerves. The wasted muscles often show a reduction in the size of their fibres, and an increase of connective tissue—fibrous myositis. The spinal cord may be healthy, but in almost all cases examination by modern methods shows changes in the nerve cells and degeneration in the tract fibres derived from the posterior roots.

**Symptoms.**—As might be expected from the composition of the peripheral nerves, the symptoms of polyneuritis may consist of disorders of movement, sensation and autonomic function, and these disorders are symmetrical and typically begin in the peripheral portions of the limbs and spread proximally. The relative severity of these disturbances varies from one variety of polyneuritis to another, and the detailed symptomatology of each variety is more fully considered below. The motor disorder is in all instances a lower motor neurone paralysis, with the characteristic weakness, reflex loss and tendency to wasting of the muscles: a marked propensity to contracture is universal. Bilateral drop foot is in a large number of cases the first objective motor manifestation. The sensory disorders are similarly peripheral and symmetrical and may involve both superficial and deep sensibility and may be both positive (pains and paræsthesiæ) and negative (anæsthesiæ). The first complaint is usually of numbness in the feet and in the hands, and this extends proximally, and is soon accompanied by objective sensory loss, which by reason of its mode of development soon has characteristically a "glove and stocking" distribution. In some varieties the autonomic

defects are seen in alterations in sweat secretion and trophic changes in the skin, nails and other tissues.

The tendency to myocardial weakness which has already been mentioned, though characteristic only of certain varieties, should be borne in mind in all cases.

The cerebrospinal fluid in the infective types of polyneuritis contains an excess—usually a great excess—of protein, the globulin fraction also showing an increase; the other elements of the fluid are normal, except that in rare cases of acute infective polyneuritis cellular increase may be found.

**Diagnosis.**—The diagnosis of polyneuritis from other diseases rarely presents serious difficulty. It is made from the combination of symmetrical flaccid paralysis with sensory loss of the "glove and stocking" distribution, and tenderness of the muscles and nerves, confined to, or most intense in, the distal part of the limbs. A variable degree of polyneuritis is an associated feature of subacute combined degeneration of the spinal cord, and this disease may easily be confused with polyneuritis. The differential clinical features are given on p. 1553 and, as pointed out there, the distinction at an early stage, may in some cases be made with confidence only by examination of the blood for the characters of pernicious anemia. The development of extensor plantar reflexes is an absolute point against polyneuritis, while a great excess of protein in the cerebrospinal fluid is equally against subacute combined degeneration. When sensory disturbances and diminished tendon reflexes are prominent symptoms and muscular weakness is slight, *tabes* may be suggested, and the resemblance is still greater when ataxia is present. Difficulty usually arises when the distinction has to be made between *tabes* and alcoholic neuritis, in a patient who has courted both diseases. In most instances the diagnosis can be made from the nature and distribution of the sensory changes. The lightning pains of *tabes* cannot be mistaken by anyone who is familiar with their peculiar characters. Anæsthesia of the extremities is common to both diseases, but diminished sensibility around the nose and across the chest is peculiar to *tabes* and is present in almost every case. In neuritis the calf muscles and nerve trunks are tender, whereas in *tabes* the sensibility of these structures is usually greatly diminished. Hyperæsthesia to touch and temperature, and great exaggeration of the abdominal reflexes, also suggest *tabes*. Examination of the cerebrospinal fluid usually puts the diagnosis beyond doubt.

Rarely does polyneuritis come on with such rapidity as to simulate poliomyelitis. When it does so the occurrence of any peripheral sensory loss may reveal its nature, and the absence of cells in the cerebrospinal fluid shows that the illness is not poliomyelitis.

**Course and Prognosis.**—In a few instances myocardial failure or respiratory paralysis brings about a fatal issue at the height of the illness. Otherwise the normal course of the disease is a stage of invasion followed by a stage of recession, leading to complete recovery. The duration of these varies greatly according to the ætiology of the malady. In rare cases recovery fails to occur and in the chronic hypertrophic types of the disease this is the rule.

Disability after recovery from the neuritis may result from muscular contractures, wasting or neuritic pains.

**Treatment.**—The first essential is to remove the patient from the influence of the exciting cause. In alcoholic cases, rigid precautions are necessary to prevent secret access to alcohol. To attain this, treatment in an institution is almost a necessity. In most instances when the cause, whatever it may be, is removed, gradual improvement sets in and complete recovery ensues, in a time that varies with the severity of the symptoms. During this time the physician's most important duty is to prevent the occurrence of deformities and contractures. From the beginning each joint in the affected limbs should be moved passively to its full range several times each day, and care should be taken to ensure that the attitude of the limbs during rest is a suitable one, especially that the feet are maintained at right angles to the legs by the use

of appropriate apparatus. Drawing up of the heel must be prevented at all costs.

Gentle massage is soothing in the acute stage, provided muscular tenderness does not preclude it. Later, more vigorous rubbing may be given, and the patient should be encouraged to move the limbs voluntarily. Electricity is seldom called for. Analgesic drugs and soothing applications may be needed at the onset. Thereafter local treatment to the limbs is combined with measures to improve the patient's general condition.

The administration of vitamin B<sub>1</sub> preparations has now a great vogue in the treatment of both multiple (parenchymatous) and interstitial neuritis. In the latter its use has no theoretical justification or practical value, and even in the former, though its use is rational it yet remains to be proved that the course of the malady is materially influenced. This may be due to inadequacy of dosage in the past, and the parenteral injection for from 2 to 4 weeks of 1000 to 2000 units daily is the minimum dosage likely to be efficacious. Even with this dosage it is not yet clear that the course of any ætiological variety of polyneuritis is materially influenced, and extravagant claims should be treated with great reserve.

#### ALCOHOLIC NEURITIS

In former years alcoholism was perhaps the commonest cause of severe peripheral neuritis, but at present alcoholic polyneuritis is a rare disease in the British Isles. It occurs most often in women, especially in those who take small amounts of alcohol frequently, and it has often been the first indication of secret drinking. There is much evidence that the disorder results as much from the deficient diet and the chronic gastritis commonly found in alcoholic subjects as from the direct toxic effect of the alcohol taken.

The onset is insidious, and in most cases premonitory symptoms, such as numbness and tingling in the extremities or cramps in the muscles of the lower limbs, are present for several months before actual weakness occurs. Subjective sensory troubles are a marked feature, even in the early stages. Besides numbness and tingling the patients complain of feelings of excessive heat or of coldness in the limbs, or of severe aching or cutting pains in the legs. Painful cramp in the calf muscles is a common symptom. It is often worst at night, and may interfere seriously with sleep. Objective examination usually reveals sensory loss, in which the various elements of sensation are affected in a manner which is almost pathognomonic.

Stated briefly, there is anaesthesia of the skin with hyperaesthesia of the deeper structures. Light touches are not appreciated at all or many are missed, the temperature sense is defective, and the prick of a pin causes no pain, whereas even moderate compression of the muscles may cause the patient to cry out. The sensory loss is greatest in the feet and hands and diminishes towards the knees and elbows. Muscular tenderness is usually greatest in the calves. The soles of the feet are also unduly tender. Hyperaesthesia is often well marked before anaesthesia of the skin appears. To the disability caused by pains and spasms, weakness of the muscles is added in all but the slightest cases. The arms may suffer first, but in most cases the extensors of the toes, the dorsiflexors of the ankle, and the extensors of the fingers and wrists are attacked in progression, and double foot-drop and wrist-drop result. To overcome the foot-drop, the knees are raised high in walking. This gives to the gait the "steppage" character which is common to all forms of peripheral neuritis. In most cases the distal flexor muscles are also affected, but to a slighter degree. In severe cases, weakness extends to the proximal muscles and even to the muscles of the trunk. The affected muscles become soft and diminish rapidly in bulk. Unless precautions are taken, contractures occur in the flexor muscles and produce deformities of the limbs, which add greatly to the difficulties of treatment.

At the onset the knee-jerks are exaggerated, but in most cases by the time the patient comes under observation all the tendon reflexes are absent. The cutaneous reflexes may be unaltered, diminished or absent. Sphincter control is retained. Slight bilateral weakness of the face is often present but severe paralysis is rare. Ptosis, nystagmus and weakness of the external ocular muscles have been observed.

Trophic and vasomotor disturbances in the extremities are common. The hands and feet often perspire freely at first and then become unnaturally dry, and they may be white and cold or red and hot. In some cases œdema of the hands or lower extremities is present. In chronic cases the skin of the hands and fingers is thin, smooth and shiny, and the nails are ridged and brittle.

In almost every case of alcoholic neuritis there is some *psychical defect*. One form—Korsakoff's psychosis—is characteristic of and almost peculiar to this disease. The most prominent feature is failure of memory for recent events and loss of appreciation of time and place. A patient who has been bedridden in a hospital for nervous diseases for several weeks, when visited by the resident physician who has attended her daily, will "recognise" him at once as Dr. X, whom she has not seen since he brought her first child into the world some years ago. She is now, she says, in a lying-in hospital which she entered yesterday, and has just been confined with her second baby, who is in bed beside her. She also "recognises" strangers at her bedside, and connects them with events of long ago. Everything is related in the most circumstantial manner, and if the facts were not known her tale might well be accepted as truth. In most cases the mental defects are not so gross. There is merely a failure of memory, to which is added moroseness and irritability, caused by withdrawal of alcohol.

#### ARSENICAL NEURITIS

Peripheral neuritis may be caused by a single large dose of arsenic, or it may result from prolonged use of the drug in the treatment of such diseases as Hodgkin's disease, chorea and severe anæmia. It is a rare malady, and the likelihood of its appearing under the last-named conditions is negligible. The toxic action of arsenic with alcohol seemed to be greater than that of either alone.

The description given of alcoholic neuritis applies to this form as well. Hyperæsthesia of the skin and tenderness of the muscles are more constant and more severe in the arsenical form, and paralysis and atrophy of the muscles are often more widespread and more rapid in their progress. Hyperkeratosis of the soles and pigmentation of the skin are characteristic of arsenical poisoning. In a suspected case, the diagnosis can be confirmed by the discovery of abnormal quantities of arsenic in the urine or in the hair and skin.

The mental changes described in connection with alcoholic neuritis under the heading of Korsakoff's psychosis may be present, especially when repeated poisonous doses of arsenic have been taken.

#### DIPHTHERITIC PARALYSIS

The exotoxin of diphtheria is highly selective for nervous tissues, and some form of paralysis occurs in a very high proportion of the cases. The intensity of the paralysis bears no constant relation to the severity of the local infection, for cases in which the original disease has passed unnoticed may be followed by serious damage to the nervous system. Walshe has classified the nervous manifestations of diphtheria into three distinct groups, namely, the local, the specific and the generalised paralyses.

*Local* paralysis occurs in parts related anatomically by nervous connections to the site of the diphtheritic lesion. In faucial diphtheria, the local palsy appears in the palate. In extra-faucial diphtheria, e.g. infected sores on the limbs, the local palsy appears in the muscles supplied by the segments of the cord to which afferent nerves

from the infected focus pass. The reason for this is, that toxins elaborated by the diphtheria bacillus ascend from the primary focus to the cord or the medulla. Having reached the central structures, they diffuse to neighbouring motor cells and, by injuring them, cause paralysis of the muscles they supply. Paralysis of the palate therefore does not occur except in faucial diphtheria.

The *specific* manifestation of diphtheria is paralysis of accommodation. Like trismus in tetanus, it is not due to a local lesion, but occurs in many cases, whatever the site of origin of the toxins. It is present in cases of both faucial and extra-faucial diphtheria, and is the local effect of exotoxin accepted from the general blood-stream.

The third or *generalised* form of diphtheritic paralysis is multiple neuritis. It follows extra-faucial as well as faucial diphtheria, and is also a result of the action of exotoxin circulating in the blood.

As faucial diphtheria is the commonest form, the most frequent nervous symptom is *paralysis of the soft palate*. It is shown by the nasal quality of the voice and by the regurgitation of fluids through the nose. As a rule, the weakness is bilateral and equal, but in some cases it is greater on the side on which the local lesion is more severe. It makes its appearance in most instances about the end of the second week, but may come on as early as the fourth day, and as late as the sixth week. The soft palate is relaxed, and its movement on phonation is diminished. The palate may be insensitve, and its reflex is often diminished or lost. Recovery usually occurs in a few weeks. In rare instances the muscles of the pharynx and the vocal cords are paralysed. Together with palatal palsy, it is common to find marked weakness and tenderness of the sternomastoid muscles and masseters. These are also local effects.

*Paralysis of accommodation* appears about the same time as the palatal palsy, perhaps a few days sooner. The reaction of the pupils to accommodation as well as to light, can almost always be obtained. The trouble is subjective, and is shown by defects of near vision—for example, by inability to read small print. Hypermetropes suffer great inconvenience. In myopes it may pass unnoticed. Paralysis of any of the extrinsic ocular muscles with strabismus and diplopia may occur, and this may be either nuclear or peripheral in type.

*Multiple neuritis* usually comes on 3 to 6 weeks after recovery from the throat infection. Its presence is often detected when patients begin to exert themselves during convalescence. Weakness and aching pains in the legs, unsteadiness in walking, clumsiness in performing fine movements with the hands, feelings of pins and needles in the extremities—all these are common early symptoms. Weakness affects in varying degree the muscles of the neck, trunk and limbs. It is generally slight in degree, greater in the lower than in the upper extremities and greater in the extensor muscles than in the flexors. Marked local atrophy is uncommon. In severe cases, life may be endangered by paralysis of the intercostals and of the diaphragm, but fortunately one set of muscles has usually begun to recover before the other is seriously affected. The small muscles of the hands and feet and the muscles of the calves and forearms are almost always tender on pressure. They are soft and flabby, and often show a partial reaction of degeneration.

Sensory ataxy is almost always present, and is often severe when the paralysis is trivial. It causes the patient great inconvenience, as it interferes seriously with walking and with the finer movements of the hands. Objective examination reveals sensory impairment of the "glove-and-stocking" type. On the hands and feet, the loss to light tactile stimuli is often complete, pain and temperature being less affected. As the limb is ascended, sensation gradually becomes normal. Even when the sensibility of the skin is but little diminished, the sensations of position and of passive movement in the extremities are often seriously impaired, and the sense of vibration is often lost.

In the early stages and for a few days the tendon-jerks are exaggerated, but are lost later in every case. Their return is often long delayed, and it is common to see

patients months after recovery of normal power, in whom the knee-jerks are still absent. It is common also to find them absent many months after an attack of diphtheria in patients who give no history of nervous symptoms during the attack. The skin reflexes are usually retained, and stimulation of the sole gives a normal response.

Cardiac failure is a grave but uncommon complication. It is of myocardial origin. Vasomotor paralyses and disturbances in the nutrition of the skin, which occur so often in other forms of peripheral neuritis, are never seen in diphtheria. In those that survive the attack, complete recovery from the nervous troubles always occurs.

#### ACUTE FEBRILE POLYNEURITIS

**Synonym.**—Acute Infective Polyneuritis.

At various times small epidemics of a form of polyneuritis characterised by a febrile onset and by the involvement of the facial nerves have been described (Osler, Gordon Holmes, Rose Bradford and others).

Nothing is known of its aetiology and it is probably not essentially different from Landry's paralysis in nature, though less fulminating in onset and not so liable to grave involvement of the trunk muscles.

The onset is with slight fever, headache and malaise, pains in back and limbs, and such general symptoms as a coryza or gastro-intestinal irritation. The fever persists for 2 or 3 days only. A few days then elapse before the signs and symptoms of polyneuritis develop. It is said that the proximal limb muscles are more severely involved than the distal muscles, a point of distinction from other forms of polyneuritis, but this relative incidence of weakness is not invariable and has probably been over-stressed. The trunk muscles do not escape, and the face is often bilaterally paralysed. As in other forms the paralysis is of the lower motor neurone type, flaccid, atrophic and with loss of tendon-jerks. Sensory loss is very slight, and there is relatively slight muscular tenderness. The cerebrospinal fluid may show a high rise in the protein content, but is otherwise normal.

The clinical course is variable, and sometimes fluctuating in the individual case. Death may ensue from paralysis of the respiratory muscles, but recovery in the majority of cases is fairly rapid. There is the usual tachycardia of polyneuritis. If the patient survives the acute phase, complete recovery ensues.

#### DIABETIC NEURITIS

In many patients with glycosuria, symptoms are present which point to changes in the peripheral nerves. In some cases the only symptom is neuralgic pain in the distribution of one or more nerves. This is commonest in the lower limbs, where it simulates sciatica, and sugar is found in the urine in the absence of any other sign of diabetes. In other cases, a single large nerve trunk suddenly becomes paralysed.

In severe diabetes the knee-jerks and ankle-jerks are diminished or lost in more than half the cases. This may accompany subjective sensory troubles in the lower limbs, or it may appear as an isolated symptom. The muscles are very often tender and the vibration sense of the feet is frequently absent. To objective examination, the sensibility of the skin is usually intact. Perforating ulcers of the feet have been observed. Only in very rare instances does the neuritis proceed to the stage of generalised peripheral paralysis of motor and sensory structures.

#### PROGRESSIVE HYPERTROPHIC POLYNEURITIS

Dejerine and Sottas described an extremely rare progressive form of polyneuritis, sometimes developing in infancy, showing an heredo-familial incidence, and characterised by thickening of the nerve trunks due to hypertrophy of the sheaths of

Schwann. In recent years other cases of hypertrophic polyneuritis have been described which have no hereditary or familial character. There is evidence that some, at least, of the cases described under this heading were examples of primary amyloidosis of the peripheral nervous system.

**Pathology.**—The thickening of the nerves may be palpable during life, but is not invariably so. Microscopically this thickening is found to be due to masses of non-nucleated tissue arising from the sheath of Schwann.

**Symptoms.**—The malady develops and progresses very slowly with peripheral weakness, muscular wasting, sensory loss, loss of tendon-jerks. There may be noted, in addition, kyphoscoliosis, nystagmus and ataxy of movement. It was formerly thought that the Argyll Robertson pupil was an integral part of the symptom-complex, but this is not the case.

**Prognosis.**—Death ultimately ensues from intercurrent disease.

**Treatment.**—There is no known treatment which is effective.

## LEAD PALSY

The nervous effects of lead poisoning are confined almost entirely to motor neurones. Subjective sensory disturbances are often slight or absent, and in most instances there is no objective sensory loss.

**Pathology.**—Aub in 1923 showed that the first event was the local concentration of lead in those muscles which were about to be paralysed and that the paralysis was a muscular event primarily, and that, secondarily, the lead ascends along the motor axons and may finally cause the death of the ventral horn cell. The degenerative changes in the nerves are confined almost entirely to the motor fibres, and are most intense in the intramuscular twigs supplying muscles of the extensor groups. Normal and degenerated fibres are found side by side, the former becoming more numerous as the nerve is traced upwards. Degenerative changes due to the action of lead are also found in the affected muscles.

**Symptoms.**—In most cases of the common *antebrachial* or *wrist-drop* type, paralysis is limited to the extensor muscles of the fingers and wrists—that is, to the muscles supplied by the *musculo-spiral* nerve. But the *brachio-radialis* and the *abductor longus pollicis*, also supplied by this nerve, usually escape. Inability to extend the first phalanges of the two middle fingers, owing to weakness of the common extensor, is usually the first difficulty. The special extensors of the index and little fingers, the long extensors of the thumb and the extensors of the wrist are next attacked, and the characteristic *wrist-drop* appears. As a rule the paralysis becomes severe about a week after it is first noticed. By this time it is usually bilateral and symmetrical, but for several days, or even for several weeks, it may be confined to one side. The affected muscles waste rapidly and the back of the forearm becomes flattened, thus rendering the intact *brachio-radialis* more prominent. In this form, loss of power always precedes atrophy, and some muscles may show weakness without any wasting. Recovery is almost always complete. Simple weakness without atrophy usually passes off in a few weeks. If the wasting is moderate and the muscles still react to faradism, recovery may be expected in a few months. When the atrophy is severe, a year or more may elapse before recovery is complete.

Occasionally the *deltoid*, *biceps*, *brachialis* and *brachio-radialis* muscles are affected, either alone or in company with the *forearm muscles*—*upper arm* or *brachial* type. Less often paralysis occurs in the legs, the muscles supplied by the *peroneal* nerve, namely, the long extensors of the toes and the *peronei*, being chiefly involved—*peroneal* type. Like the *brachio-radialis* in the arm, the *tibialis anterior*, although supplied by the *peroneal* nerve, usually escapes. This type is usually associated with paralysis of the forearm muscles, and runs the same course.

In the form of paralysis described above the features are similar to those of a traumatic lesion to a nerve. Loss of power precedes, and may be more extensive than wasting, faradic irritability of the muscles is lost or diminished while the reaction to galvanism is retained, and recovery is usually complete. It is therefore called the degenerative form. In the second form, the paralysis has the characters of progressive muscular atrophy. Weakness and wasting come on together, faradic and galvanic irritability of the muscles are both diminished in proportion to the wasting, and the paralysis is often permanent. This is known as the primary atrophic form. It occurs especially in the small muscles of the hand—*Aran-Duchenne type*—but is sometimes irregular in its distribution and affects many muscles in all four limbs. It is often associated with the first form, but may occur alone. Wasting comes on slowly, and accompanies the loss of power, instead of succeeding it. It is much more intractable than the degenerative form, and often persists after muscles showing the first form of paralysis have recovered. (See also Lead Encephalopathy, p. 368.)

### LANDRY'S PARALYSIS

In the year 1859 Landry applied the name "acute ascending paralysis" to a case in which acute flaccid paralysis with loss of reflexes and without sensory disturbances commenced in the periphery of the lower limbs, and rapidly spread upwards. The arms were next involved, first in the periphery, and later the trunk, respiratory muscles, neck and lastly the cranial muscles were involved, and death occurred from respiratory failure. He made a careful microscopic examination of the spinal cord with the methods then at his disposal, and failed to detect in it any morbid changes. He subsequently described this symptom complex, which has since borne his name, from an analysis of ten cases.

Since this time a large number of cases have been recorded which, from the acute nature of the onset, and from the spreading nature of the paralysis, have been described as cases of Landry's paralysis. This name should be restricted to those cases of acute spreading paralysis, in which disorders of sensibility and sphincter trouble are absent or little marked, and in which recovery is complete if the patient survives, and in which no gross lesion is found within the nervous system after death.

Acute poliomyelitis may also, in rare cases, give rise to a spreading paralysis, and cause much difficulty in diagnosis; but it is invariable that some permanent paralysis remains upon recovery, and, further, the lesions of poliomyelitis are both gross and characteristic.

**Ætiology.**—What is known of the causation of the disease in general resembles very closely that of acute polyneuritis. It affects males much more frequently than females, and occurs chiefly in adult life between the ages of 16 and 54 years.

**Pathology.**—Slight hyperæmia of the spinal cord, and especially of the grey matter, with a few punctiform hæmorrhages, is the only change noticeable upon naked-eye examination. Very definite histological changes are found upon microscopic examination in the anterior horn cells and in the cells of Clarke's column, where any degree of change may be found, from an early pericentral chromatolysis to a complete loss of the chromatin granules and concentration of nuclei.

The cerebrospinal fluid is clear. It may present no abnormality either as regards cell or albumin content. In other cases there is an excess of albumin, and in this respect it resembles the cerebrospinal fluid of polyneuritis, which is usually albuminous, and sometimes so highly so as to clot spontaneously. In a few instances the fluid contains numerous lymphocytes.

**Symptoms.**—The onset is in some cases abrupt, with the appearance of the characteristic spreading paralysis. Much more frequently the paralysis is preceded by certain premonitory symptoms, which may last from a few hours to days or weeks.

These symptoms may consist in malaise, headache, lassitude, insomnia, anorexia, constipation, gastralgia, vomiting and diarrhoea, and there is not infrequently slight elevation of temperature. More characteristic still among the prodromal signs are subjective disturbances of sensibility. Pains in the back and limbs are common, and may be of a dull aching nature, or they may be sharp and shooting in character. Numbness, tingling, "pins and needles" and other paræsthesias may occur over any part of the body, and are most commonly complained of in the periphery of the limbs. The muscles may be locally tender during this prodromal stage.

It is not uncommon for the paralysis to commence in the periphery of the lower extremities, to ascend rapidly and to involve the muscles in the order of their innervation from the spinal cord, the trunk becoming affected before the upper extremities, and the intercostal muscles before the diaphragm. The muscular weakness may commence in any group of muscles, as, for example, in the face, neck, upper extremities or trunk, and when so commencing the spread of the paralysis is downwards, constituting a descending type of paralysis.

In Landry's paralysis, as in acute polyneuritis, the innervation of the respiratory muscles seems to be peculiarly resistant to the toxin.

In those cases which recover the advance of the paralysis ceases, and those muscles which have been most recently affected begin to show some recovery quickly.

When the disease does not prove fatal either from respiratory failure, pulmonary complications or sudden syncope, the paralysis ceases to spread, and the patient enters upon the stage of recovery.

The paræsthesiæ, which have been described with the onset, often persist, and there may be cramp-like pains. Not uncommonly the muscles are tender upon deep pressure; but there is never that severe degree of tenderness met with in some forms of peripheral neuritis as, for example, in alcoholic neuritis. There is exceptionally blunting of sensibility, most marked in the periphery; but this is never deep, and is rapidly transient.

Though from the general weakness of the trunk muscles there may be some difficulty in emptying the bladder and rectum during the first few days, and even retention with overflow incontinence that may require catheterisation from the same cause, yet these last but a few days. The deep and superficial reflexes disappear early with the onset of the first signs of the paralysis in the affected regions. The psychic functions remain unimpaired throughout.

**Diagnosis.**—The rapidly spreading character of the paralysis in Landry's disease is so striking as to necessitate distinction only from those few maladies in which a similar rapidly spreading paralysis may occur, and these are acute spreading myelitis, intrathecal hæmorrhage, acute poliomyelitis (spreading type) and acute polyneuritis. Acute spreading myelitis is at once distinguished from Landry's paralysis by the severe sensory loss and sphincter paralysis, which in the former condition develop *pari-passu* with the motor paralysis and, further, if the myelitis does not involve the lumbo-sacral enlargement of the spinal cord, an extensor plantar reflex will be observed.

The rare, spreading form of poliomyelitis presents difficulty in diagnosis, especially in the acute stage. The general symptoms and the pyrexia are apt to be more severe in poliomyelitis. An onset in childhood is more suggestive of poliomyelitis than of Landry's paralysis. A fairly high polymorphonuclear leucocytosis in the blood, and a lymphocytosis in the cerebrospinal fluid, are in favour of poliomyelitis. The persistence of local atrophic palsy on convalescence is absolute evidence of poliomyelitis. The distinction of Landry's paralysis from acute febrile polyneuritis depends on the mode of spread of the paralysis, and on the possible presence of numerous cells in the cerebrospinal fluid.

**Prognosis.**—In about one-half of the cases the paralysis advances until the respiratory and bulbar muscles are involved, and death occurs from respiratory failure, usually on the third or fourth day, but sometimes not until 10 days or more have

elapsed. So long as the paralysis is extending, and especially when the respiratory and bulbar muscles are failing, the prognosis is very grave. The extension of the paralysis may, however, cease at any stage, and when this occurs the prognosis at once becomes favourable, even though there be considerable involvement of the respiratory and bulbar muscles.

**Treatment.**—The patient must be placed at complete rest, and the discomfort and panic which are likely to arise from the utter inability to move must be assiduously relieved by frequent changes of posture. The greatest care must be taken that the patient is adequately fed with nutritious and light food. Stimulants are usually indicated. A mercurial aperient should be administered early and the bowels regularly relieved, for in some cases obstinate constipation occurs. The bladder should be catheterised, if there is difficulty in micturition. Both pain and pyrexia may be relieved by the administration of salicylates or aspirin.

Atropine tends to check accumulation of secretion within the bronchi. Oxygen may be administered where cyanosis occurs, and it may be necessary to place the patient in a Drinker respirator. When once there are signs that the malady has passed its height, and that recovery is commencing, little treatment is required except careful nursing and feeding. Gentle massage may then be employed.

## MUSCULAR DISEASES

### PRIMARY MUSCULAR DYSTROPHIES

**Synonym.**—The Myopathies.

Under this heading, a disease is described in which the voluntary muscles undergo primary degeneration, independent of detectable disease in other parts. To facilitate description, a number of clinical types have been distinguished according to the age at which the disease appears, to the group of muscles first attacked, to the presence or absence of pseudo-hypertrophy, and to the prominence of the hereditary factor. The chief of these are—(1) the pseudo-hypertrophic type; (2) the juvenile type of Erb; (3) the facio-scapulo-humeral type of Landouzy and Dejerine; (4) the distal type.

The first type is fairly constant, but there is in reality no sharp division between the different forms. That the others do not represent separate diseases is proved by the appearance of more than one of them in members of the same family. The disease is familial, and it is also hereditary in the sense that it may appear in some or all the members of a family through several generations.

The changes in the muscles in the myopathies are essentially the same as those which occur when muscles degenerate from any other cause, namely, a slow and progressive atrophy of the contractile elements, with a concurrent increase of fat and fibrous tissue. However in most cases of myopathy swelling or hypertrophy of some of the muscle fibres is a feature of the microscopic picture, and this hypertrophy is believed to represent an early stage of the degenerative process. In the pseudo-hypertrophic form the connective-tissue hyperplasia is excessive in some of the affected muscles and their bulk is increased. In the other forms of the disease, and in those muscles in the pseudo-hypertrophic form which become weak without any increase in size, the overgrowth of connective tissue may balance the loss of bulk due to atrophy of the contractile tissues, and the diseased muscles retain their normal size; or atrophy may proceed faster than hyperplasia, and the muscles waste from the beginning.

#### 1. PSEUDO-HYPERTROPHIC MUSCULAR DYSTROPHY

**Ætiology.**—The cause of the disease is unknown. In many instances no antecedent cases can be traced in the family. In others, a family history is obtained,

always on the mother's side. Isolated cases occur, but more often several children are attacked in each generation. Boys suffer more frequently than girls in a proportion of about 5 to 1. Sometimes one sex alone suffers, sometimes both. It is rare for all the children to be attacked. The males who escape beget healthy children, whilst the females, who appear to have escaped, may transmit the disease to some of their offspring.

**Symptoms.**—The symptoms appear in early childhood. The onset is often delayed to the fourth or fifth year, rarely until towards puberty, and very rarely until as late as the twentieth year. In cases of late onset, enlargement of the calves has usually been present for many years. Weakness appears first in the muscles of the pelvic girdle. The child, who usually looks fat and strong, begins to walk late, he falls easily and rises again with difficulty. He does not romp as other children do. He cannot skip or jump, and he has great difficulty in mounting stairs. At first the muscles may be normal in size, but, as a rule, some show obvious enlargement before the fifth year is reached. The enlargement is most conspicuous in the calves, the buttocks and the infraspinati. The erector spinæ, the quadriceps in whole or part, the deltoid, the supraspinatus and the triceps often show considerable hypertrophy. Occasionally the masseters are enlarged. At the same time other groups of muscles atrophy. This is most severe and most frequent in the latissimus dorsi and in the lower part of the pectoralis major. Later it extends to other muscles, and ultimately to those which were at first hypertrophied. The neck and face are spared. There is no exact correlation between the size of the diseased muscles and their power, but weakness is usually greatest in those which show most atrophy. The defects are greater in the proximal muscles, and diminish distally. The hands often retain good power to the end. This distribution of paralysis gives rise to certain characteristic defects of attitude and movement.

In standing the legs are placed far apart, and the upper part of the trunk is thrown back, so that a plumb-line from the most prominent vertebra falls behind the sacrum. This attitude compensates for the forward tilting of the pelvis, resulting from weakness of the glutei, which normally raise the anterior border of the pelvis by lowering its posterior border. In the sitting posture the lordosis disappears, for now the attachments of the flexors of the hip are approximated, and these muscles no longer lower the anterior border of the pelvis. On lying down the lordosis appears again, but can be abolished by relaxing the flexors of the hip-joint, that is, by flexing the hips passively. In walking, the feet are widely separated, and to clear the ground with the advancing foot the body is inclined first to one side and then to the other. This "waddling" produces a gait like that seen in congenital dislocation of the hip. The early preponderance of weakness in the extensors of the hip and knee is betrayed by the great difficulty experienced in mounting stairs.

The manner in which the child rises from the supine to the erect position is almost pathognomonic of the disease. He first tries to sit up, but fails. He then rolls over on his belly, and raises himself first on his knees and elbows, and then on his hands and feet. Next he places his hands on his knees, and as it is impossible for him to raise the trunk actively owing to weakness of the extensors of the hip, he literally climbs up his thighs. Pushing the extensors may be enough to enable him to complete the movement; if not, he jerks the shoulders back suddenly and gains the erect posture by a writhing movement, whose details are difficult to follow. To climb the thighs successfully a certain amount of power is necessary to hold the knees slightly flexed. When this power is lost he is no longer able to rise. The arms are also used to assist the weak legs in sitting down and in getting up from a chair.

As time goes on the weakness increases, and invades all the muscles of the trunk and limbs. Some of the muscles become shortened, and distortions are produced by permanent alterations in the position of the joints. The knees and elbows become

flexed, the feet take up the attitude of talipes equinus, the spine becomes curved and the whole body is grossly deformed.

The deep reflexes and the electrical excitability of the muscles diminish gradually as the wasting increases. Sensation is unaffected. The sphincters are not involved. The mental condition shows no abnormality.

**Diagnosis.**—The diagnosis is usually simple if a few of the outstanding features of the disease are known. The defects of attitude and movement, especially the mode of rising from the supine position, together with the characteristic association of enlargement of the infraspinati and calves with atrophy of the latissimus dorsi, form an unmistakable combination.

**Prognosis.**—This is most grave. Few patients reach adult life, and most die within 10 years of the onset of the disease.

**Treatment.**—Drugs have no beneficial influence. Glycine in large doses has been advocated but there is no reliable evidence that it affects the course of the disease. Massage and passive movement are useful in the prevention of contractures, and the efficiency of the muscles may be prolonged by suitable exercises. Walking should be practised daily, until it becomes impossible. Very often this is lost owing to contractions of the calf muscles, and is regained after tenotomy.

## 2. OTHER TYPES OF MUSCULAR DYSTROPHY

**Ætiology.**—The separation of the remaining types of myopathy from the pseudo-hypertrophic form is not an absolute one, as isolated cases are occasionally met with which seem to form a connecting link between the several varieties. The varieties, however, are habitually separate in occurrence, and in families in which numerous cases conforming to the types to be described hereunder have occurred throughout several generations, no cases presented the peculiar features of the pseudo-hypertrophic form. Moreover, the sex incidence as well as the period of onset is different in the two varieties, and it is possible that there is some essential pathological difference between them, and that they are separate diseases. With regard to the types of myopathy unassociated with pseudo-hypertrophy, no doubt exists as to their fundamental unity. They are merely varieties of one disease.

The influence of heredity is much more prominent than in the pseudo-hypertrophic form. Isolated cases occur, but they are rare. In most instances several members of a family are affected in the same and in succeeding generations.

The sexes suffer equally. The time of onset varies within wide limits—from infancy to old age. When the wasting begins in the face (*facio-scapulo-humeral type*) the disease frequently begins in childhood; but sometimes it begins there late in life. In the cases where it is first noticed in the muscles of the shoulder and pelvic girdle the onset is most frequent between the ages of 15 and 35 (*Erb's juvenile type*); but here, again, it may begin in childhood or early old age, and the term juvenile is hardly applicable to it. The same variations in the age of onset are noticeable in cases where the atrophy begins in the forearms and legs (*distal type*).

The various types may be exemplified in members of the same family, and in the same family the age of onset may show extreme variation.

The cause of the disease is quite unknown.

**Symptoms.**—In the so-called juvenile form weakness and wasting come on simultaneously. In most cases they are first noticed in the arms; but in some families the legs suffer first. Of the arm muscles the biceps, triceps and brachio-radialis are most often first affected. The lower part of the pectoralis major, the latissimus dorsi, trapezius and rhomboids are attacked in most cases. Atrophy of the serratus magnus is common; but it may escape even in severe cases. The deltoid, supraspinatus, infraspinatus and subscapularis usually escape. Atrophy of the forearm and hand muscles is rare.

In the legs, the flexors of the hip, the extensors of the knee and the glutei are most frequently affected. The muscles below the knee often escape entirely.

In the face the zygomatic muscles and the orbicularis are attacked. The face is dull and expressionless, the naso-labial fold is obliterated, the lips are habitually separated and the lower lip projects—myopathic facies. The face does not light up in conversation, in blinking the eyes are incompletely closed, and the articulation of labial consonants is defective. In smiling the mouth forms a straight line, instead of its angles being drawn upwards and outwards by the zygomatici. The power of whistling is lost. When the patient closes his eyes, or compresses his lips as forcibly as he can, they can be forced open with great ease. The buccinators are often affected, the tongue and the masticatory muscles never. The spinal muscles often atrophy, and in a few cases the abdominal muscles have been involved. The excitability of the muscles to faradic and galvanic stimulation usually diminishes in proportion to the wasting. The muscles never show fibrillary tremors. Sensibility is unaffected, and all the other functions of the nervous system are normal. Deformities are neither so common nor so severe as in the pseudo-hypertrophic form.

**Diagnosis.**—In isolated cases the diagnosis of myopathy from spinal progressive muscular atrophy is based upon the distribution of the wasting, upon the disproportionate weakness and the absence of fibrillation in the affected muscles and the age of the patient. When a family history of atrophy is obtained, dystrophia myotonica and peroneal muscular atrophy must be excluded. Dystrophia myotonica is distinguished by the peculiar prolonged response of some of the muscles to voluntary, electrical and mechanical stimulation, and by the distribution of the wasting. Atrophy of the sterno-mastoids, which is constant and severe in dystrophia myotonica, is never seen in the forms of myopathy now under consideration. In peroneal muscular atrophy the combination of atrophy in the lower limbs and small muscles of the hands, together with sensory disturbances in the lower limbs, is distinctive. In an early case, when the hand muscles are still normal and sensory changes are absent, the differentiation from myopathy may be impossible for a time.

**Prognosis.**—The disease shows wide variations in its course and duration. The atrophy may remain confined to the group of muscles in which it begins, or extension may take place after an interval of several years. It rarely extends beyond the muscles mentioned above. In most cases, even in those that begin in childhood, progress is extremely slow, and as no symptom of the disease is necessarily fatal, death usually results from other maladies unconnected with the disease.

**Treatment.**—Owing to the variable course of the disease, it is impossible to estimate the value of any treatment that may be employed. Massage, and especially voluntary exercises designed to bring the weakened muscles into play, seem sometimes to retard the progress of the disease.

## AMYOTONIA CONGENITA

**Synonyms.**—Oppenheim's Disease; Myotonia Congenita.

**Definition.**—A malady of early childhood, usually congenital and sometimes familial, characterised by extreme flaccidity, smallness and weakness of the muscles, which are not actually paralysed, by lowering of the faradic excitability of the muscles, by loss of the tendon-jerks and by contractures in the region affected.

**Ætiology.**—In most cases the disease is present at the time of birth; in a few cases it has appeared during the first year of life in an apparently healthy child, and sometimes following an acute illness, such as bronchitis or diarrhœa. Usually sporadic, it has occurred in several children of the same parents. Some authorities consider that it is a variant of the Werdnig-Hoffmann disease (*q.v.*) (p. 1565).

**Pathology.**—The chief morbid changes are found in the muscles. In these very

conspicuous pathological conditions are present, closely resembling those found in the myopathies. The three most striking conditions are—(1) the minute size of the majority of the muscle fibres, from  $7\mu$  to  $12\mu$ ; (2) the presence of a few very large or "giant" fibres reaching  $140\mu$  in diameter, and larger than any fibre occurring in normal muscle; (3) marked regressive changes in the giant fibres. There is increase of the connective tissue between the muscle bundles. Reduction in numbers of the ventral horn cells of the spinal cord occurs, and the ventral roots are small and poorly myelinated.

**Symptoms.**—The extreme flaccidity of the affected muscles is noticed from the time of birth. They are small and weak, and though there is no muscular wasting and no absolute paralysis, yet in many cases the limbs cannot be raised against the action of gravity, nor can the head be held up. The great relaxation of the muscles and ligaments allows of the most fantastic attitudes being assumed without pain. When the child gets older, he is unable to sit up, but when placed in the sitting position the spine bunches up from absence of any muscular support, and he is unable to support his weight upon the weak legs. The amyotonia is symmetrical, and affects the legs always, the trunk often, the arms not infrequently, but never the face. Notwithstanding the flaccidity, some degree of flexor contracture is usually present. The faradic excitability of the muscles is much lowered, but not lost. Sensibility and the sphincters are not affected. The superficial reflexes are normal, but the deep reflexes are invariably absent in the affected regions. The children are usually intelligent, with good bodily development and growth proceeds normally.

**Diagnosis.**—This presents no difficulty on account of the presence of the flaccidity at birth, the absence of the deep reflexes and the tendency slowly to improve. It has to be separated from those maladies to which it bears a superficial resemblance, namely, the myopathies, rickety weakness, obstetrical, infantile and diphtherial palsies.

**Course and Prognosis.**—Some of the children succumb during the early and severe stages of the disease, but the tendency of the disease is to improve slowly in the course of years, and in some cases almost complete recovery with return of the knee-jerks occurs.

**Treatment.**—This consists in aiding the natural tendency to improve with massage, passive movements and exercises, in treating contractures with tenotomy and in attending to the general health and nutrition.

## DYSTROPHIA MYOTONICA

**Synonym.**—Myotonia Atrophica.

**Definition.**—A disease of familial incidence, which begins usually in the third and fourth decades of life, and which is characterised by muscular atrophy of peculiar distribution and unlike that of any other disease. This atrophy occurs first and most in the sterno-mastoids and facial muscles, next in the muscles of the forearms, and may also be found in the muscles of mastication, in the vasti, and in the dorsiflexors of the feet and peronei. Associated with this wasting, but not commensurate with it, nor necessarily occurring in the same muscles, is a peculiar difficulty in relaxing the muscles after effort, called "myotonia", which gives to this malady an especial feature which at once separates it from all other forms of muscular atrophy. Signs of bodily dyscrasia are often present, the most important of which are cataract, premature baldness, atrophy of testicles, loss of sexual power and general bodily wasting. This disease was first placed upon a firm clinical basis by Batten and Gibb, and Steinert in 1909. Curschmann in 1912 adopted the term *Dystrophia Myotonica* as being more correctly descriptive.

**Ætiology.**—This condition is probably always familial, and the heredity is homologous—that is, it is transmitted from the same child-rank, in a number of

apparently unconnected families at a common distance from one and the same ancestor, and often it seems to be entirely confined to one child-rank. The descent of the latent tendency is equally through the males and females, but the males more frequently transmit. The presence of the heredo-familial disease in earlier generations is often betrayed by other signs, such as cataract, frequent celibacy, childless marriages, high infant mortality and a dying out of certain branches of the family. The malady has been observed at the age of 10 years, but usually the onset occurs between the ages of 20 and 35 years. A large number of the patients have been unusually gifted and proficient in athletics prior to the onset. Both sexes may be affected. No exciting causal factors are known.

**Pathology.**—No definite changes have been found in the nervous system. The muscles presenting the myotonia have repeatedly been examined and found normal. In the atrophic muscles the morbid process singles out certain fibres especially, so that thick and thin fibres are found lying together. There is increase of the muscle nuclei round thick and thin fibres alike, though some atrophic fibres may be found with no increase of nuclei. Recent biochemical and electrographic studies by Brown and Harvey of a form of congenital myotonia in goats suggest that there is no functional disorder of neuromuscular transmission of the motor impulse, but that the disorder is in the muscles themselves.

**Symptoms.**—The onset is gradual and the course extremely slow. The first symptom to call attention may be, either the difficulty in relaxing after muscular effort—the clinging of the hand to the tool which has been grasped, the smile that is so slow to disappear—or the weakness and wasting of the muscles. The two chief signs of the disease—the myotonis and the wasting—seem to have no connection the one with the other, either as regards coincidence in time or place. The myotonia may appear years before there is any obvious wasting. Moreover, the muscles which show the most conspicuous myotonia are often those which are not wasted, and finally those muscles which waste greatly tend to lose any sign of myotonia which they may have had. The extent and the intensity of the muscular atrophy and of the myotonia show great variations. The atrophy may be widely spread, and many muscles may be myotonic, or the former may be severe and the myotonia slight, or both may be present in minor degree only. Lastly, there are cases in which only the atrophy or only the myotonia is present. The myotonia consists in an inability to relax a muscle immediately after it has been put into voluntary contraction, and the greater the effort used in contracting the muscle, the greater the difficulty with relaxation. The patient grasps one by the hand, and is unable to disengage the hand, but pulls it away still grasping, and it may take seconds to relax. He smiles quickly to a suitable stimulus, and the face remains fixed at the height of the smile for long after the emotion has vanished. In eating, his jaw becomes fixed, he is unable to perform alternating movements in the muscles which are affected except at a very slow rate. When the myotonia is severe and general, he is liable to fall like a log when walking, from inability to relax muscles which have been put into contraction. The myotonia is seen most often and to a greater extent in the flexor muscles of the forearm and in those of the face, but it may be quite general. In the same patient it may be very marked at one time and absent at another. The muscular weakness and wasting usually have a most typical distribution, involving the sternomastoids and other muscles of the neck, the facial and masticatory muscles—giving rise to the sad "myopathic" face, the vasti of the thighs, the dorsiflexors of the feet and the flexor muscles of the forearms, and this is the usual order in which the muscles are affected. It is always in one or other of these groups that the wasting commences, but sometimes the sequence of muscles attacked is quite different. Fibrillation does not accompany the atrophy. The electrical reactions show a reduction both to faradic and to galvanic stimuli, with a tendency to a polar change. The "myotonic reaction" consists in a very long-lasting contraction when the muscles are-stimulated with every

form of stimulus, and if the latter be strong it may last as long as 30 seconds. This is usually present in the muscles which are myotonic and not wasted and some modification of it is often superadded to the other electrical changes in those muscles which are wasted.

The affection of the muscles of the face and jaw entails some alteration of articulation and phonation. The voice is low, it lacks intonation and has a definite nasal quality. Sensibility is not affected.

The rule is for the tendon jerks to be diminished or lost, and it is very rare for all the jerks to be present in any case.

Apart from symptoms and signs connected with the muscles, the most important sign of the dystrophy is cataract, which occurs in more than half of the cases. This cataract is often met with in otherwise healthy brothers and sisters of those who have the muscular changes, and in otherwise healthy members of earlier generations in the afflicted families. In succeeding generations after its first appearance, the age of occurrence of this cataract shows remarkable "anticipation"—that is, commencing at first as senile cataract, it appears at an earlier and earlier age with each successive generation, until with fully developed myotonia atrophica it appears in youth. The presenile cataract of the dystrophic generation begins as small peripheral opacities, first in the posterior and later in the anterior cortical lamellæ, sometimes with fine point-like opacities scattered through the lens. It ripens quickly to a total soft cataract, with a small central nucleus.

The genital organs remain infantile in some cases; celibacy and childless marriages are common. More often sexuality is normal until the onset of definite symptoms, after which desire and power disappear, and ultimate atrophy of the testicles is usual. Early frontal baldness is the rule. A general wasting of all the tissues of the body is seen in many cases.

**Diagnosis.**—There is no difficulty in the diagnosis when the distribution of the muscular atrophy is typical and when myotonia is obvious; it simply involves a recognition of the unique characteristics of the disease. When the myotonia precedes the wasting, the age of onset will distinguish this malady from Thomsen's disease, myotonia congenita, and the oncoming of any sign of facial weakness or muscular wasting will make the diagnosis certain. When the myotonia does not appear until long after the wasting is apparent, the diagnosis is much more difficult, but the wasting of the sternomastoids is characteristic.

**Course and Prognosis.**—This malady usually progresses very slowly, but occasionally very extensive and incapacitating wasting of muscles and weakness may develop within a year of the first symptom. Some cases seem to remain stationary for very long periods. The tenure of life is certainly short in all cases, and does not appear to be prolonged beyond the middle of the fifth decade. The oldest patient reported in the records as still living was aged 50 years.

**Treatment.**—It has been found that the administration of quinine, gr. 10 to 15 daily, lessens the myotonia considerably. Neither electrical treatment nor massage has the slightest effect in altering the course of the disease.

## MYOTONIA CONGENITA

**Synonym.**—Thomsen's Disease.

**Definition.**—A very rare malady, commencing in early childhood, which is hereditary and familial, and characterised by a striking slowness in the relaxation of the muscle after voluntary effort. On voluntary contraction the muscles pass into a spasm which relaxes very slowly, resembling the contraction of the veratrinised frog's muscle, and its subsequent slow relaxation. Peculiar changes in the electrical excitability of the muscle and hypertrophy of the muscle fibres are constant.

**Ætiology.**—Beyond the facts that the malady is usually hereditary and familial, only a few sporadic cases occurring, and its incidence in early childhood, nothing is known of the causes. Cold, heat, fatigue and hunger conspicuously increase the symptoms.

**Pathology.**—The affected muscles are actually hypertrophied, and are always firmer to the feel than normal muscles, while sometimes they show a board-like hardness. The individual fibres show considerable hypertrophy.

**Symptoms.**—The presence of the disease first becomes evident from slowness, clumsiness and awkwardness of movement, with a great tendency to fall if the balance is upset. This is often most noticeable after rest, when, on attempting to move, the limbs seem glued down and move very slowly. Often the patient is able with exercise to work the stiffness off, and the myotonia lessens in the muscles which are being used; but if he is suddenly called upon to put another set of muscles into action, as, for example, by losing his balance, he is at once caught up by the myotonia and so is apt to fall. In other cases the myotonia increases or is uninfluenced by exertion. The muscles of the legs are, as a rule, most affected, but sometimes all the muscles of the body may be involved.

Passive movement does not reveal the presence of any rigidity. The abnormality affects only the relaxation of the muscles after voluntary contraction, the peculiar feature being the slowness of relaxation due to the continuance of the contraction of the muscle fibres for a variable number of seconds after voluntary impulses have ceased. The peculiarities of electrical excitability bear the name of the "myotonic reaction" of Erb. The contraction, either on faradic or galvanic stimulation, lasts much longer than the normal and relaxes very slowly, and this is more marked the stronger the current used; with the application of galvanism, slow wave-like contractions of the muscle are seen to proceed slowly from the cathode to the anode. There is no pain, no sensory disturbances or loss and the sphincters and reflexes are unaffected.

**Diagnosis.**—The only malady which can be confused with Thomsen's disease is dystrophia myotonica, in which the myotonic symptoms and signs are identical. In the latter malady, the onset is at a much later age, the incidence of the spasm is upon local groups of muscles, and the characteristic weakness of the facial muscles and atrophy of the sternomastoids, etc., at once distinguish it.

**Course and Prognosis.**—Thomsen's disease has no tendency to shorten and destroy life. It tends to become more marked from infancy to puberty, and then less marked again as age increases. It has never been known to recover spontaneously.

**Treatment.**—No cure for the disease is at present known. The administration of quinine hydrochloride, in doses of gr. 10 to gr. 15 by mouth t.d.s., may give considerable symptomatic relief. Conditions which increase the myotonia, such as cold, fatigue and hunger, should be avoided. Most patients are the better for regular exercise, as was observed by Thomsen, who was himself afflicted with the disease.

## MYASTHENIA GRAVIS

**Definition.**—A chronic malady of adult life characterised by an excessive fatigability of the voluntary muscles, especially those innervated by the cranial nerves. This leads to a variable paralysis of the muscles concerned, which is brought on or rapidly increased by exertion, and tends to improve with rest, but which may ultimately become permanent.

**Ætiology.**—The malady seems to have become more prevalent in this country during the past 30 years. It affects predominantly young adults between the ages of 20 and 30. It very rarely occurs before puberty, but cases beginning in middle or late life are by no means as uncommon as was formerly supposed. The sexes

are equally affected. Nothing is known of any causal factor, either immediate or remote, though the first onset of symptoms has not infrequently been noted after an acute infection, particularly of the naso-pharynx. The one clinical association which cannot be ignored is with exophthalmic goitre, for not only may myasthenia follow that disorder but the ocular palsies and muscular weakness which may occur in Graves' disease bear no small resemblance to those of myasthenia.

**Pathology.**—The only change found within the nervous system, either central or peripheral, is slight atrophy of those nerve cells which supply long paralysed muscles, and these changes are certainly not primary. Nor is there any essential histological change in the affected muscles except where long-standing complete paralysis is associated with the degeneration of long disuse. Small aggregations of lymphocytes, known as lymphorrhages, have been described in the muscles in some cases.

In a large proportion of the cases subjected to autopsy some degree of persistent thymus has been found. This may vary between a well-formed organ weighing several grammes and small remnants or thymic rests. These thymic elements may show evidence of proliferation or degeneration.

Chemical examination reveals no significant disturbance in the metabolism of glucose, calcium, phosphorus or creatinine, although, in common with most muscular disorders, creatinuria may be present in myasthenia. There is evidence that the muscle potassium is increased, and that it reverts to normal when the myasthenic symptoms are abolished by an injection of neostigmine.

The view expressed in earlier editions of this book that the seat of the disorder of function responsible for myasthenia gravis is at the myo-neural junction has of recent years received confirmation from observations made with physostigmine and the synthetic substance neostigmine (Prostigmin). It is believed that the normal transmission of impulses from the motor nerve fibres to the voluntary muscles through the motor nerve endings depends upon the liberation at the end-plate of acetyl-choline. In myasthenia the failure of effective innervation may be due to the inadequate liberation of acetyl-choline, or to its premature or excessive destruction by choline esterase, or to the presence of a curare-like substance antagonistic in its action to acetyl-choline. The administration of physostigmine temporarily delays the destruction of acetyl-choline by the choline esterase normally present in the blood, and during the period of its activity renders muscular contraction normal. The exact nature of the defect still awaits elucidation.

**Symptoms.**—The onset of the disorder is usually insidious but in rare cases may be acute. The symptoms can all be related to excessive fatiguability of muscles, and thus make their appearance after use and improve with rest, and are most severe in the evening and least marked on first waking in the morning. The muscles first affected are usually those innervated by the cranial nerves, particularly the external ocular muscles, but as the disease progresses the extent of the disorder spreads to involve the muscles of the neck, limbs and trunk. Sometimes, however, the characteristic weakness is universal from its commencement.

Ocular symptoms are of the greatest importance. The clerk finds that towards the end of the day he is seeing double, or that one or both upper eyelids droop. In the morning on waking the ptosis and diplopia have both disappeared, only to return after another day's work. The school teacher notices that as he lectures his voice gradually grows weaker and more husky, and acquires a nasal quality. This too clears up with a rest, and is invariably worse towards the end of the day. Difficulty in swallowing is a common symptom. At the commencement of a meal all may be well, but as it goes on the food is forced down with increasing difficulty until finally swallowing is no longer possible. Many patients find that they can eat their solid meals only in the early part of the day, and by evening can at best sip fluids. Nasal regurgitation of fluids towards the end of the day is common. The act of chewing

may give rise to so much fatigue of the masticatory muscles that only soft foods can be taken, and towards the end of a meal the lower jaw may be too heavy for the exhausted muscles to sustain, and the patient may be seen supporting it with the hand and attempting in this way to supplement the process of mastication. The muscles of the face commonly share the weakness. Friends observe that towards the end of the day the patient's face is expressionless, or comment on the peculiar "snarling" quality of the smile. The patient may complain that he cannot smoke a cigarette or whistle, as the lips cannot maintain a sustained pressure. In severe cases the eyelids can only be closed with difficulty, and it may be noticed that the patient sleeps with the eyes open. Fatigue of the neck muscles may be an early symptom. The head feels more and more heavy and finally can only be supported with the aid of the hand. The weakness may affect any or all of the muscles of the limbs and trunk, though the arms are more frequently involved than the legs. The soldier may find that after a few minutes rifle drill becomes impossible, or the schoolmaster that after writing on the blackboard for a short time he is no longer able to support the weight of his arm. Women may complain that they cannot keep their arms up long enough to do their hair. Whatever the initial presenting symptom may be, the extent of the disorder gradually spreads until a wide range of voluntary movements is affected.

Few diseases present a more characteristic picture than does myasthenia gravis in its established stage. The variable and usually asymmetric ptosis is seldom absent. It can readily be brought on or increased by asking the patient to look upwards for a few seconds, and when severe one or both eyes may be fully closed. Unlike the ptosis of tabes, there is little compensatory wrinkling of the forehead, because the frontales share the weakness of the levatores palpebrarum. The ocular palsies are characteristic; any or all of the external ocular muscles may be involved, and strabismus is common. The paralyses rapidly increase in severity and extent with ocular movement, and a few attempts to glance from side to side may bring all oculomotor activity to an end. The pupils are always normal in their reactions. The ocular more than any other muscles show a tendency to develop complete and unvarying paralysis in long-standing cases, and, with the exception of the extremely rare disorder described as progressive nuclear ophthalmoplegia, there is no disease other than myasthenia which gives rise to a complete external ophthalmoplegia with normal pupils in the absence of other signs of nervous disease. Fortunately when the stage of permanent ophthalmoplegia is reached the optic axes are usually parallel and diplopia disappears.

The facies of myasthenia, with its lack of expression, the inability to close or pucker the eyes or to wrinkle the forehead and the peculiar, weak, nasal smile, is unmistakable. Weakness of the muscles of palate, pharynx and larynx may be general or localised, and at first is present only after use. Permanent paralysis of the soft palate is commonly seen in chronic cases, that of the vocal cords or pharynx being much more rare. Severe weakness of the tongue may be associated with some reduction in the size of the organ but with this rare exception wasting is not seen in myasthenic muscles, nor are the tendon reflexes disturbed. Sensibility and sphincter functions are unimpaired. The excessive tendency to fatigue which is responsible for the symptoms of myasthenia is also seen in the muscles in their response to electrical stimulation. With an interrupted faradic current the contraction of the muscles is at first normal, but instead of remaining at a similar strength for an indefinite period it rapidly decreases until it disappears altogether. If the stimulation is discontinued for a few minutes and then recommenced, there is a further response, which tires more readily than the first. After exhaustion by faradism, some volitional response remains.

**Diagnosis.**—This is seldom a matter of difficulty if the variable paralysis, increasing with fatigue and improving with rest, is conspicuous, for this phenomenon

occurs in no other disease. Even so, in its early stages, the malady is often mistaken for a hysterical disturbance. More legitimate difficulty may arise when only isolated and permanent paralysis is present, especially as such cases are liable to present themselves in ophthalmic or laryngological departments. It should be remembered that any unilateral or bilateral palsy of muscles supplied by the cranial nerves may be myasthenic. Here the history of slow onset, with variable paralysis and fatigue phenomena, can nearly always be obtained, and the absence of the usual signs of gross lesions of the brain-stem nuclei, or of progressive diseases affecting the latter, should avoid confusion. When, as sometimes happens, myasthenia begins with a unilateral ophthalmoplegia or laryngoplegia, the diagnosis may be really difficult. The possibility of such should be borne in mind, and a careful watch kept for the appearance of conclusive evidence. An intramuscular injection of 1 ml. of the standard solution of neostigmine may be used as a diagnostic test, its effect being to bring about within half an hour the temporary abolition or very great amelioration of any variable symptoms that are due to myasthenia gravis.

**Course and Prognosis.**—Although myasthenia gravis is invariably a dangerous disease, as its name implies, its course is extremely variable. In some cases the degree of the muscular involvement steadily increases in extent and severity until a fatal outcome is reached in a few months or years. In such cases death usually results from progressive respiratory failure or from aspiration broncho-pneumonia consequent upon pharyngeal and laryngeal palsy supervening upon a state of inanition. Not infrequently death is sudden and unexpected and appears to be due to syncope. In other cases, the disorder may remain confined for a long period to small groups of muscles, particularly those of the eyes, and may result in a condition of multiple cranial nerve palsies of an unvarying character with a survival period of 20 to 30 years. In such cases more generalised and active symptoms may reassert themselves at any time, and death may occur after many years of stability. In yet a third group, long periods of complete remission may occur, ultimately followed by a recurrence of characteristic symptoms, which on this occasion may prove to be progressive.

**Treatment.**—The treatment of this disorder was revolutionised by the discovery of the specific effect of physostigmine and its synthetic relative neostigmine. Few things in medicine are more dramatic than the sudden amelioration of symptoms, the relief of ptosis, the recovery of ocular movement and the return of facial expression, that follows the administration of one of these drugs. The effect is, however, transitory, lasting only from 4 to 6 hours, and is in no sense curative. It is usual to administer 2 to 4 ml. of neostigmine (1 to 2 mg.) subcutaneously two or three times daily half an hour before meals. If the drug causes abdominal discomfort or palpitation it may be combined with atropine sulphate gr.  $\frac{1}{16}$ . Alternatively, the drug may be given by mouth in doses of 10 to 25 mg. three or four times daily. In severe cases the period during which the effect of the drug is wearing off may be attended by severe and alarming weakness, and over a prolonged period the beneficial action of the drug tends to lessen and an increased dose is required to be effective. The administration of ephedrine gr.  $\frac{1}{2}$  to 1 b.d., has been found beneficial; it may be sufficient of itself to keep a mild case in reasonable comfort or it may be used as an adjunct to neostigmine.

The frequent association of a persistent thymus with myasthenia has long received attention and has led to attempts to treat the disorder by influencing this organ. Numerous isolated examples of improvement in symptoms following radiotherapy to the thymus are recorded in the literature, but the results were not constant. Of recent years a number of cases have been treated by surgical removal of the thymic remnants, with encouraging results. This operation is one which carries a considerable mortality, and should only be attempted by an expert in thoracic surgery. Of the patients who have been so treated some have shown a degree of improvement amounting to a cure and quite different from anything seen with neostigmine therapy.

Others, after a period of improvement, have relapsed. Others, again, have shown no material alteration in their condition. The procedure should at present be regarded as an encouraging but not yet fully established advance in treatment.

## FAMILIAL PERIODIC PARALYSIS

**Definition.**—A flaccid paralysis affecting the muscles of the trunk and of the extremities, associated with loss of the deep reflexes and diminution or loss of faradic excitability in the muscles. The paralysis is temporary in character, though it may be fatal during the attack, and it recurs at intervals. It is a rare malady, some 200 cases having been reported in the literature.

**Ætiology.**—It has been noted as early as the fifth year, and as late as the thirtieth year; but usually it appears about the age of puberty. Most of the cases occur in the male sex. Heredity is very marked, and the malady has been traced through five generations. Transmission may occur either through the male or through the female, and not infrequently a generation is skipped. Several members of the same family are usually affected.

**Pathology.**—Several cases have come to necropsy, but no lesion which could be associated with the symptoms was found. Biopsy of the muscles has given entirely negative results. During an attack, significant fall in the serum potassium has been demonstrated. An attack may be brought on by a large intake of glucose, especially if an injection of insulin is given at the same time.

**Symptoms.**—The clinical picture is so striking as to be almost dramatic. The patient retires to bed feeling perfectly well, and awakens in the morning without pain or malaise, but with a flaccid motor paralysis, which always involves all four extremities, and which may reach all the muscles of the body, except those of the organs of speech, deglutition and respiration, and even these are often partially involved. Severe involvement of these vital muscles during an attack has caused death. The bladder and rectal functions are retained, and it is unusual for the patient either to void urine or fæces during the attack. The paralysis is usually at its height on waking; but it may subsequently increase. After fasting for a variable time, from a few hours to a few days, it passes off, sometimes gradually, sometimes rapidly. In one family it was astonishing how the patients on waking in an attack could judge invariably how long the particular attack would last. They could judge with unfailing certainty when ability would return, and were in the habit of arranging their business accordingly. Most of the patients in addition to the severe attacks of paralysis suffer from what they call "morning weakness", temporary inability to grip with the hands, and slight disability with the feet on waking. The paralysis in periodic paralysis is flaccid, and there is loss or marked diminution of response to faradism during the paralysis. The deep and superficial reflexes are lost in the paralysed region. Objective sensation is not affected; but there may be subjective sensations of tingling and numbness, and the muscles may be a little sore and stiff after the attack. Flushing of the face and profuse sweating may occur during an attack. There is an invariable tendency for the attacks to diminish in frequency and severity after middle life is reached.

**Diagnosis.**—This must be evident to any one acquainted with the symptoms of the disease.

**Treatment.**—Potassium chloride in large doses (up to gr. 30 or 40) will avert or cut short an attack. No other remedial measure is known.

## SECTION XIX

# PSYCHOLOGICAL MEDICINE

### INTRODUCTION

PSYCHIATRY is concerned with forms of illness as widespread and diverse as those of somatic medicine. There are almost as many beds in mental hospitals, colonies for defectives and allied institutions as in all other hospitals put together; and there is an undoubtedly large, if unnumbered, part of the population who have mild mental disorder not needing mental hospital care: hysteria, obsessional neurosis, hypochondria, chronic depression, paranoid states and so forth. The diversity of this widespread group of illnesses depends on their being disorders of mind—disorders, that is, of the human function which comprehends and sums up all other functions of the organism, serves to relate a human being to his complex environment, and is the chief token that he is an individual, and not a sample. Mental disorders are therefore varied, as are the people who suffer from them. It is only by ignoring most of what is individual in these illnesses that a few common types or categories can be recognised, comparable to the "diseases" of somatic medicine. Such a procedure is necessary for practical ends; material must be classified. Moreover, a biological foundation may be assumed for the syndromes with which psychiatry works. They stand for the main ways in which a human being can become mentally unhealthy. There are only a few such ways, and they are determined by the structural and functional patterns inherent in the organism. Diversity arises through their becoming manifest under the influence of each individual's special environment and in combination with his other inherited tendencies. Diversity, therefore, can be due to a combination of single hereditary causes and to the effect of each individual's environment throughout his life upon his development and behaviour. There is always interplay between inheritance and environment. Part of the psychiatrist's business is to discover how this interplay has led to the present illness. The interplay, moreover, is sufficiently varied in the course of each patient's life to make prognosis and the effect of treatment a matter of individual study, rather than of summary inference from the diagnosis, once made.

Treatment is only another special instance of the environment acting on the patient; its power and limitations for him cannot be judged without considering what effects this or that experience has had on his previous life. Consequently the psychiatrist, even more than the general physician, must study illness in two ways: first, as showing some typical pattern of morbid behaviour with characteristic pathological changes, and tending to run along well-known lines; and secondly, as a patch of personal biography, something to be understood, rather than classified in terms of psychology and physiology. The two methods are complementary, though, in a brief textbook presentation, the former must be the more prominent.

There is no dividing line between somatic medicine and psychiatry. Psychiatry, although it has to work in part with social and psychological conceptions of which general medicine has hitherto felt less need, suffers greatly when it limits itself to this way of regarding mental phenomena. It cannot safely ignore the relationship between bodily happenings and the patient's state of mind. Crude instances of this relationship are the delirium that accompanies an acute fever and the irritable fatigue (neurasthenia) that may follow it; the insanity that is due to cerebral tumour or general paralysis of the insane; the obsessional neurosis that follows encephalitis lethargica; and the hysterical symptoms of disseminated sclerosis. There is no

mental disorder, mild or severe, in the causation of which bodily disease may not play an important part. Moreover, it is not only in crude instances of structural or chemical disease that the relationship between bodily and mental illness may be recognised. A human being does not exist as a rarefied mind united with a solid body; he is an organism all of whose subsidiary functions contribute to this highest function—his mind—which brings him not only consciousness, but also an integrated behaviour in relation to his surroundings. Disturbances, transient or permanent, of these part-functions (for example, in the sensory apparatus or the circulatory system) will have some effect on his state of mind. Changes in the central nervous system are the most obvious instance of this, but the endocrine glands, the autonomic nervous system and the metabolic processes are often of notable significance in the various maladjustments summed up as mental disorder. A human being is constantly responding to, and influencing, his surroundings; but his doing so is conditioned by the various parts of his body and the way they are working. It is likewise, and equally, necessary to weigh psychological influences and effects when deciding the pathogenesis or the treatment of predominantly physical illness. The part that emotion may play in the chain of events that cause or aggravate peptic ulcer has been lately demonstrated in a manner to convince the sceptic, and there is less dramatic but equally weighty evidence attesting the interplay between psychological and physical happenings which may influence the outcome of many a surgical or other illness. Much of the recent enthusiasm for "psychosomatic" medicine turns on a belated recognition of this. It is plain that psychiatric issues must be the concern of all doctors, not merely the psychiatrist's preserve; and that psychological happenings differ from physiological in their deceptive accessibility to familiar methods of observation, in their almost Gordian complexity, and in the concepts found most useful for describing and explaining them, rather than in any essential quality which would keep them permanently distinct.

Before the categories and clinical features of mental illness are described, the principles of psychopathology, prognosis and treatment call for some very brief consideration, since without them psychological medicine written down is a repellent catalogue of details. Though the principles set forth may seem trite or too obvious to be worth stating, it is unfortunately the case that they are often not applied as fully as they might be to the clinical study and treatment of mental disorders.

**Psychopathology.—INTRINSIC CAUSES.**—The intrinsic causes of mental disorder are those which depend on heredity and on phases of development, e.g. the climacteric. Extrinsic causes, which come from the environment, are either mental experiences or physical damage. The distinction between intrinsic and environmental, like that between physical and mental, is convenient but artificial; a long sequence of related happenings both within and without the patient's body goes to the causation of any mental illness. It is, of course, possible in many instances to discover some indispensable link in this chain of causes—an intoxication with alcohol, for example, a syphilitic infection of the brain, an inherited predisposition to periodic insanity, a bereavement—which may legitimately be singled out as the chief cause and classified as intrinsic or extrinsic, but this is more valuable for formal and didactic purposes than clinically. Actual cases usually show a complicated aetiology. Thus, a man whose parents had both been subject to melancholia became himself profoundly depressed after the death of his wife, and attempted suicide by drowning. He survived, but during the resulting pneumonia he was delirious and threw himself from an upper window, crying out that he must go to his wife. The causes of the mental disturbance in this case were many and obvious; numerous they always are, but not always obvious. One cause may, of course, be prepotent.

The more detailed the analysis of a patient's endowment and experiences, the more entangled physical and psychological, internal and external factors seem to be.

**Heredity and constitution.**—The hereditary factor is not a general neuropathic

taint; there are specific predispositions to one or other anomaly. These predispositions are transmitted in accordance with familiar genetic principles, summed up in the modern gene-theory of inheritance. Studies of families and of twins have proved the importance of the hereditary factor in the major non-organic psychoses, though they have not yet sufficed to reveal with certainty the number and location of genes concerned in the transmission of the hereditary types of morbid reaction.

Among the main reasons for this incompleteness in our knowledge is the impossibility of concluding that an inherited trait is not present, merely because it is not manifest in some recognisable form. Other inherited factors and, most of all, the environment, will in many cases determine whether an individual predisposition is to become evident or not. Thus a man may have an inherited tendency to melancholia which remains latent until a financial reverse or disease of the cerebral arteries provides the conditions necessary for its manifestation. It is true that some inherited predispositions, *e.g.* to Huntington's chorea, are almost independent of the environment in this respect, but such are exceptional.

More than one type of proneness to mental disorder can be inherited by the same person. He may, for example, be prone not only to periodic insanity, but also to schizophrenia. Mingled proclivities of this kind account for anomalous clinical pictures, frequently met with and difficult to classify as either one syndrome or another. The "either-or" kind of diagnosis is often out of place or misleading in psychiatry because of the commonness with which more than one constitutionally rooted type of illness may be found in the same patient. Syndromes are frequently combined; to grasp their clinical meaning one may have to investigate the patient's family not only as to mental disorder, but as to normal characteristics of temperament also.

The signs of a transmissible tendency to some mental disorder may not be actual illness, but only a special kind of personality. There are certain varieties of personality which show some of the essential features that characterise certain types of mental illness; the differences between personality and illness seem then to be of degree rather than of kind. Moreover, those who manifest one or other type of illness are often found to have had the type of personality that is functionally similar to it. So close may the similarity be that it is difficult to decide when the illness has begun, because there was no sharp dividing line, in time or in form, between the more or less normal previous personality and the actual disorder. This frequency of association and similarity of form between the normal state and the illness points to the constitutional background of mental illness, and shows how hereditary tendencies can express themselves in more or less normal ways in personality before the catastrophe of an obvious illness has directed attention to them. Nor is it only in the personality that inherent proclivities may be revealed; certain types of bodily structure, too, occur much more frequently in those with a particular mental constitution or mental illness than in the rest of the population. The most striking instance of this is the frequency with which a "pyknic" bodily habit and a "syntonic" personality are found among those who have periodic attacks of mania or melancholia (see p. 1646). It is not common to find pure examples of mental or physical types in the population, and recent work, *e.g.* that of Sheldon, has aimed at making it possible to designate the mixture of components in any individual by a taxonomic formula rather than by ascribing them all to one or other type; but whatever method of description be employed, the association of osseous and muscular structure with a particular personality structure and perhaps with a predominant form of autonomic response seems frequent enough in healthy as well as mentally ill persons to warrant classing physique, physiological behaviour and personality together, however tentatively. Such constitutional features, whether mental or physical, indicate that inherited tendencies can body themselves forth in normal physical and psychological structure before morbid exaggerations of them make an appearance. The varieties are some-

times called by appropriate names, e.g. schizoid, cyclothymic, syntonio, obsessional, hysterical, paranoid. The relationship is not a simple one. There are very many people with these types of personality who never fall mentally ill.

A pronounced personality, belonging to one or other of these types, does not indicate that the person who exhibits it is likely to have a mental illness, but only that if he should have a mental illness, it will probably be of the corresponding type. As with all inherited anomalies of which the crude manifestation is delayed until adult life, there may be for many years none or only mitigated signs of the proclivity; these may be indistinguishable from what occurs in normal people. The more pronounced the anomaly of personality, the more likely that it portends a mental illness, or, at any rate, a proclivity to the mental illness in specially adverse circumstances.

In studying personality, the psychiatrist can have recourse to several techniques, besides direct observation and the descriptive method based on the reports of those familiar with the individual studied. The most ambitious are projective methods, of which the Rorschach ink-blot and the thematic apperception test are examples. The patient's fantasy is evoked by more or less standardised stimuli, and inferences drawn from what he says and does in these circumstances. Expert and cautious interpretation is indispensable. This applies to the whole of the growing array of psychological methods of assessing personality.

In the foregoing, personality and constitution have been spoken of as though they were static, innate attributes of the human organism. Neither of these epithets, however, is appropriate, not even in respect of bodily constitution. Responsiveness and plasticity are essential to human development of every kind; there is a constant interplay of personality with the outer world, modification of it and by it. The main pattern of development is doubtless determined by innate, inherited factors—bodily structures grow, instincts come into play and the general direction of functional activity is predetermined. But general directions and main patterns mean little unless they are given body and content by individual experience. Nutrition, for example, can deflect the body from its ordained pattern or enable its fulfilment; all sorts of physical interference can maim it or improve it: the same is profoundly, if obviously, true of the mental side of human growth and maturity. Consequently, each patient's personality is not to be assessed as conforming to a frozen artificial type, but as a complex of dynamic functions, changing in outward form, sometimes in unstable equilibrium, and none the less powerful for being subterranean. Here, as was said earlier of psychiatry in general, there must be two ways of viewing the data: in classes, and as individual living biographies to be understood rather than schematised. Both methods are necessary to any complete psychopathology.

*Phases of development.*—A concrete instance of the foregoing is the change that occurs at certain turning-points, such as puberty, pregnancy or the climacteric. Endocrine and other physical changes at these epochs may be accompanied by psychological disturbances, the severity and form of which bring them under the notice of the psychiatrist. They are dramatic episodes in a lifelong process of growth, maturity and involution or decay, which is marked by plasticity and development of varied functions in the first stage, stability and differentiated adaptation in the second, emotional lability and suspicion, intellectual narrowing, rigidity, failing grasp and memory, in the last. The mental disturbances which may occur at different ages are much influenced by these intrinsic factors and tendencies.

*EXTRINSIC CAUSES.*—The outer world impinges on human beings from the day of their birth, or even their conception, in more and more complicated ways, as they themselves become more complicated. In other words, the environment is, for the individual, as complicated as he can make it; and that will depend on how far he has himself developed hitherto. Human beings deal selectively, not merely passively, with experience. At each stage of their growth, previous experience helps to determine what they will select from their environment, and how they will use this and

taint; there are specific predispositions to one or other anomaly. These predispositions are transmitted in accordance with familiar genetic principles, summed up in the modern gene-theory of inheritance. Studies of families and of twins have proved the importance of the hereditary factor in the major non-organic psychoses, though they have not yet sufficed to reveal with certainty the number and location of genes concerned in the transmission of the hereditary types of morbid reaction.

Among the main reasons for this incompleteness in our knowledge is the impossibility of concluding that an inherited trait is not present, merely because it is not manifest in some recognisable form. Other inherited factors and, most of all, the environment, will in many cases determine whether an individual predisposition is to become evident or not. Thus a man may have an inherited tendency to melancholia which remains latent until a financial reverse or disease of the cerebral arteries provides the conditions necessary for its manifestation. It is true that some inherited predispositions, e.g. to Huntington's chorea, are almost independent of the environment in this respect, but such are exceptional.

More than one type of proneness to mental disorder can be inherited by the same person. He may, for example, be prone not only to periodic insanity, but also to schizophrenia. Mingled proclivities of this kind account for anomalous clinical pictures, frequently met with and difficult to classify as either one syndrome or another. The "either-or" kind of diagnosis is often out of place or misleading in psychiatry because of the commonness with which more than one constitutionally rooted type of illness may be found in the same patient. Syndromes are frequently combined; to grasp their clinical meaning one may have to investigate the patient's family not only as to mental disorder, but as to normal characteristics of temperament also.

The signs of a transmissible tendency to some mental disorder may not be actual illness, but only a special kind of personality. There are certain varieties of personality which show some of the essential features that characterise certain types of mental illness; the differences between personality and illness seem then to be of degree rather than of kind. Moreover, those who manifest one or other type of illness are often found to have had the type of personality that is functionally similar to it. So close may the similarity be that it is difficult to decide when the illness has begun, because there was no sharp dividing line, in time or in form, between the more or less normal previous personality and the actual disorder. This frequency of association and similarity of form between the normal state and the illness points to the constitutional background of mental illness, and shows how hereditary tendencies can express themselves in more or less normal ways in personality before the catastrophe of an obvious illness has directed attention to them. Nor is it only in the personality that inherent proclivities may be revealed; certain types of bodily structure, too, occur much more frequently in those with a particular mental constitution or mental illness than in the rest of the population. The most striking instance of this is the frequency with which a "pyknic" bodily habit and a "syntonic" personality are found among those who have periodic attacks of mania or melancholia (see p. 1646). It is not common to find pure examples of mental or physical types in the population, and recent work, e.g. that of Sheldon, has aimed at making it possible to designate the mixture of components in any individual by a taxonomic formula rather than by ascribing them all to one or other type; but whatever method of description be employed, the association of osseous and muscular structure with a particular personality structure and perhaps with a predominant form of autonomic response seems frequent enough in healthy as well as mentally ill persons to warrant classing physique, physiological behaviour and personality together, however tentatively. Such constitutional features, whether mental or physical, indicate that inherited tendencies can body themselves forth in normal physical and psychological structure before morbid exaggerations of them make an appearance. Nutrition, for example, can deflect the body from its ordained pattern or enable its fulfilment; all sorts of physical interference can maim it or improve it: the same is profoundly, if obviously, true of the mental side of human growth and maturity. Consequently, each patient's personality is not to be assessed as conforming to a frozen artificial type, but as a complex of dynamic functions, changing in outward form, sometimes in unstable equilibrium, and none the less powerful for being subterranean. Here, as was said earlier of psychiatry in general, there must be two ways of viewing the data: in classes, and as individual living biographies to be understood rather than schematised. Both methods are necessary to any complete psychopathology.

*Phases of development.*—A concrete instance of the foregoing is the change that occurs at certain turning-points, such as puberty, pregnancy or the climacteric. Endocrine and other physical changes at these epochs may be accompanied by psychological disturbances, the severity and form of which bring them under the notice of the psychiatrist. They are dramatic episodes in a lifelong process of growth, maturity and involution or decay, which is marked by plasticity and development of varied functions in the first stage, stability and differentiated adaptation in the second, emotional lability and suspicion, intellectual narrowing, rigidity, failing grasp and memory, in the last. The mental disturbances which may occur at different ages are much influenced by these intrinsic factors and tendencies.

*EXTRINSIC CAUSES.*—The outer world impinges on human beings from the day of their birth, or even their conception, in more and more complicated ways, as they themselves become more complicated. In other words, the environment is, for the individual, as complicated as he can make it; and that will depend on how far he has himself developed hitherto. Human beings deal selectively, not merely passively, with experience. At each stage of their growth, previous experience helps to determine what they will select from their environment, and how they will use this and

integrate it, to serve in its turn as the partial determinant of further growth and integration (the other determinants being innate ones). "Experience" is here being used in the widest sense to denote the response of a human being to the impact of the outer world upon him, whether it be consciously recognised as such or not at the time.

It is, therefore, impossible to give adequate consideration to any aspect, including the psychological, of a human being's way of dealing with the outer world unless one pays regard to his previous experience, mental and physical, and to the present state of his whole organism, mental and physical. The cultural milieu in which he has grown up must be taken into account. Too partial a regard for subsidiary functions, whether physiological or psychological, may lead one away from the living human being, who is an integrated organism, not a collection of disparate mental and physical systems; similarly, too concentrated a gaze on this latter aspect, *i.e.* on the socially organised person, to the neglect of part-functions, may make one see only a disembodied spirit, as remote from medicine as from daily life.

*Physical experiences.*—Some external happenings influence the mental state chiefly by way of the body: infection, physical trauma, intoxication and metabolic and endocrine disturbances due, wholly or in part, to environmental influences may result in mental disorder. In many of these instances, the mental change is mediated by way of some cerebral damage, and the clinical picture is of the organic neurogenic kind, *e.g.* dementia. It would be wrong to attribute the whole of the mental disorder to the cerebral damage; but to it is referable the core of the psychosis. Some diseases have an incidence on special functions and parts of the central nervous system, which determines characteristic features in the mental picture, *e.g.* the anxious fidgetiness of the patient who has had chorea, the stiff mind and obsessional thoughts and movements of the post-encephalitic, the hysterical phenomena of the elderly arteriosclerotic patient or the man poisoned with carbon monoxide, the aphasia and apraxia of the post-apoplectic, the silly "moria" of the cerebral tumour. In the main, however, it is not possible to correlate mental symptoms with special areas or kinds of cerebral damage—partly because the brain is not the only structure concerned, partly because it acts as a whole, and also because the presumptive changes in it are too evanescent and delicate to be accessible to our crude methods of examination. Even the electro-encephalogram, which seemed to promise so much, has contributed little to the understanding of cerebral happenings in mental disorder other than epilepsy, though it is valuable in suggesting the presence or indicating the site of a lesion, *e.g.* in the temporal region.

To limit oneself to the brain in studying the somatic correlates or basis of mental phenomena would be an error. In the physical accompaniments of emotion, the whole body participates through the mediation of the vegetative nervous system and the endocrine glands. This is significant, because emotional upset is one of the most important phenomena of mental disorder. The sequence of psycho-physical happenings of which an emotional upset is the climax and the outward sign, may be started not only by some mental happening, but also by physical experiences—intoxication with a drug, or a circulatory disturbance, or a metabolic upheaval such as acute hypoglycemia. Whether, for example, this hypoglycemia comes from outside, as an injection of insulin, or arises (as it rarely may) from within the body, as a "spontaneous" deficiency, is of little consequence in its bearing on the mental disturbance engendered. The chief emphasis lies on the physical apparatus through which so widespread an affection of the whole organism can be evoked, just as in other circumstances the emphasis would lie on the psychological apparatus which serves the same end. This applies more widely than to emotional disturbances alone. Where a symptom is, on the face of it, definitely physical or definitely mental, its causation may not be inferred to be exclusively of the same order; the chief cause of, say, an anorexia may be a series of mental experiences or an attack of migraine or

a uræmia or a pituitary disease. Study of the anorexia alone cannot serve to discriminate them; not even study of the psychological state alone, or of the physical state alone may suffice. Very often the physical and psychological factors in causation are mingled inextricably—they represent, of course, different facets of the same series of phenomena.

*Mental experiences.*—Mental growth is dependent on daily experience for its material. Experience can be subdivided into perceptual, emotional and other kinds, but such a division is fictitious. The means by which daily experience is incorporated with our mental equipment and acquires an influence over our subsequent behaviour in all respects can only be understood if we avoid thinking of emotions, instincts, perceptions and other abstractions as real entities, as distinct and separately operative forces. Memory, for example, is not merely an intellectual function by which we recall a happening into consciousness in more or less verbal terms, but a device, or function, by which past happenings are able to influence subsequent behaviour; the ways in which they do so, and the form in which the earlier experience is reproduced into consciousness, will be greatly influenced by its original emotional, as well as more purely perceptual, aspects, and by other physical and mental experiences—a distressing repetition of the experience, for example, or a physical happening like concussion or cortical atrophy.

There are general needs in mental life—instinctual needs—which bring us into relation with our immediate surroundings, lead us to feed ourselves, maintain our lives, reproduce, and aim at other ends which have been variously formulated by philosophers, saints and psychologists. These biological forces, however denominated or classified, are not peculiar to human beings, but in respect of human beings are so much more accessible to minute enquiry along verbal lines, that complex conceptual systems have been built up to describe them. Comparative and experimental psychology have partly corrected unreal refinements and highly metaphorical interpretations; physiology can also help here. Unduly speculative subtleties, e.g. some psycho-analytical ones, are ill-suited to medical needs. The influence of previous experience on all subsequent behaviour is as evident in physiological happenings as in the mental field; the special language and formulations and hypotheses of psychology are not to be taken as permanently distinct from those suitable to less highly integrated functions, though much must be conceded to the special complexity and character of psychological phenomena. Such terms as projection, sublimation, conversion, symbolism, identification, repression, amnesia, perseveration, displacement of affect, cover special instances of the general relationship between inherent tendencies of the organism and their material substrate, and the influence of past on present experience and behaviour.

In dealing with the multifarious world about him, a human being is constantly obliged to select what he will perceive, and in what form he will perceive it; pure "objective" perception never occurs. To perceive things at all, he must give them meaning by relating them to himself and to his previous experience. Unless he can do this, not necessarily consciously, he is at the mercy of his environment, as a newborn baby is. Perception is therefore an active process; it has instinctual and emotional, as well as cognitive aspects. It depends partly upon memory for being able to give meaning to what it perceives; such memory need not be conscious. Consciousness, it is well to bear in mind, is only an attribute of psychological happenings, not their essence or their criterion; mental life goes on with varying degrees of consciousness attaching to it. There is no sharp division between conscious and unconscious mental life: no region called "the Unconscious" with its own rules and contents. Many of the psychological happenings most significant for psychiatry go on without clear consciousness of them, but in appropriate conditions they may be accompanied by much more, or by full, consciousness. Biologically and psychologically regarded, consciousness is an attribute, like movement or the ability to learn,

immensely important for us human beings, but not a "present-or-absent" factor decisive for our mode of mental conduct.

Perception being thus an active process, which makes use of past experience, it not only selects its material and invests it with meaning, but in doing so may distort it, and give it a special "false" meaning. Unwelcome emotions may be thus projected on to external objects or happenings, which are then regarded as hostile or contemptuous, or in some other way significantly related to one's self. This is not remote from the process in visual perception, whereby one projects the image on one's retina into the external world, and is convinced of its reality there; the further process of clothing it with emotional significance depends on one's inherent tendencies and one's previous experiences. Paranoid symptoms, ideas of reference, grandiose and self-reproachful delusions exemplify this. Hallucinations and kindred phenomena are a special instance of the interplay between material substrate (*e.g.* in cocaine poisoning), inherent tendencies (*e.g.* visual fantasies of children) and past experience (*e.g.* hallucinations of homosexual abuse or divine commands). Similarly, by fantasy and imagination the outer world can be manipulated or denied according to the heart's desire, just as by body-images of proposed movement the way is prepared for purposive muscular action. In giving meaning to present things, personal connections between them and earlier experiences are established; whether normal or morbid, this ascription of "symbolic" meaning to everyday objects is indispensable to thought, and is most striking in our use of spoken or written language, where sounds and shapes are conventional symbols for the most diverse experiences. Some of our words are personal to ourselves, and are used in an individual way; in morbidly heightened form, this process may issue in schizophrenic neologisms, or oddities of expression. Similarly an obsessional patient may feel towards some word or object a superficially incomprehensible mixture of attraction and repulsion, which is due to this word or object being the symbol of some earlier experiences that have been of great moment in his life. To see how it has come to be such a symbol calls for minute study of his earlier experiences. Physical happenings in one's own body may symbolise present emotions or earlier experience of a momentous and emotionally painful kind. A gesture of disgust may normally be evoked unconsciously by a banal happening, which has somehow become emotionally coloured by past experience. A headache or nausea may embody our dissatisfaction with a present situation. So hysterical "conversion" symptoms may reflect and symbolise an inner emotional struggle, as may also some obsessional movement, schizophrenic stereotypy or hypochondriacal fear. The body, with all its functions, is the background of psychic life, and resonates to it.

What experiences will be important in determining the form of mental symptoms, depends much on the emotional disturbance they originally provoke, and this, in turn, on the instinctual drives which they touch on and disturb. Instinctual needs may conflict, and the emotion accompanying the conflict prove so disturbing that it cannot be borne in its naked form; "repression" serves the end of making this more or less tolerable, through disguising or distributing it. So emotion may be shifted from one object to another, and paradoxical or unexpected emotions be thus aroused by objects on to which the affect has been displaced. Or energy mainly directed to plain ends, *e.g.* sexual love, may be diverted into less obvious channels, and when thus "sublimated" and mingled with features derived from other instinctual sources, its origins may be hard to recognise. Sexual needs so often conflict with others that many of the most powerful motives for the production of mental symptoms come from the struggle.

To describe the whole of instinctual life, however, in terms of sex and aggression, as has sometimes been done, is only possible if one strains the meaning of these words out of all knowledge. It is as unwise to make the sexual paramount in psychogenesis as to burke it.

The patient's present symptoms, it is clear, must be examined in the light of his earlier experience. Thus one elucidates in detail the content of his illness and some of the causes of its occurrence. In doing so it is not necessary to push back all one's enquiries to a supposedly crucial stage of early childhood. The experiences of the first 2 or 3 years of life are, like all subsequent experience, contributory to mental development, and they show certain sequences of phenomena characteristic of such development. Moreover, their relative simplicity makes it possible to recognise in these early reactions the instinctual drives, or (more correctly) the "inherited functions" which become manifest when the environment supplies the necessary material, though, of course, it cannot supply the necessary energy and direction; these last must come from within. On the other hand, the functions recognisable in the relatively simple reactions of early childhood are not the same as those which may be seen in later years when the organism is more fully grown, any more than an infant's physical structure and functions are identical with those of the more differentiated adult. The obvious continuity of the actual happenings in a human being's lifetime does not justify one in trying to analyse and reduce all adult mental phenomena into terms of child psychology, nor does clinical practice usually require it.

The effect of war and famine upon the incidence of mental illness has obvious importance. The psychiatric disorders which occur in war do not differ in kind from those of more normal times, but certain forms of disorder, especially panic, exhaustion, psychogenic semi-stupor and gross hysteria in men, become commoner and sometimes more severe. People are exposed to unaccustomed dangers; their privations are both material and emotional; they have to surrender some of their independence and individuality; and they are thrown together in groups and therefore prone to share in group-feelings and group-behaviour. It is not known whether the losses, fears, misery and other psychological burdens and cruelties of modern war and its aftermath directly lead to an increase in certifiable mental illness, though such exogenous factors as malnutrition and infectious disease which war favours may have this effect. It is, however, neurotic disorders that chiefly excite attention during war, as they are then more certain to be ascertained; they interfere with military efficiency, they can impair morale, and a far higher proportion of affected people come under medical scrutiny than is customary during peace.

**Course and Prognosis.**—The making of a correct diagnosis may in psychiatry indicate the general drift of an illness—towards recovery, chronicity, progression or relapse—but is of even less use than in the rest of medicine for showing how far this will apply to a particular patient. For this, careful study of the individual history and illness are indispensable. The prognosis can be inferred from the causes, the mode of development and the form of the disorder.

Where a known external cause has been at work, its point of attack, its severity and persistence will affect the issue. This applies equally to such "organic causes" as poisons and cerebral diseases and to "mental causes", like economic misery or frustrated love. The physician must consider how long the environmental cause has been acting, what changes it is known to produce—cell-degeneration or gloom, fibrosis or fantasy—and whether it is likely to persist. He must also ask if the patient's previous history has shown that he is specially sensitive to such a trauma. This brings in the intrinsic causes. How has the patient previously reacted to this sort of interference or to any disturbing circumstances? Has he fallen more and more into unsatisfactory habits in meeting his daily life and its difficulties? How has his whole character developed? Is there good evidence of his being able to cope with partial deviations from mental health? Has he inherited tendencies to benign or to progressive illness? Which seem to be the most useful reparative or stabilising features in his personality? How far are his struggles with the world an outcome of his intrinsic endowment, evident in various guises since his childhood, how far have they been forced upon him by an adverse milieu? How old is he? There is

that syphilis is less often contracted and earlier treated. The psychological reactions to a physical disease or blemish may be favourably modified or averted, when foreseen. It is for obvious reasons impossible to counteract mental disorder by regularly protecting the patient from physical or psychic trauma; in any case, a life guarded against risks and painful experiences would be almost certain to issue in mental ill-health, out of its very emptiness. By altering a patient's environment and way of living one may, however, be able to avert an impending illness: only study of the individual patient can show how this end may be achieved. Making the patient's environment easier for him may be difficult in some instances because doing so would conflict with his obligations toward other people; and even if, on balance, a change of this sort seems essential, the patient may thereafter be troubled by guilt and shame. This is particularly evident in unsettled times.

*The work people do and the conditions under which they do it influence their mental health.* By ensuring that good vocational advice is available to those about to enter the field of employment and to those whose maladjustment is connected with their occupation, useful preventive work can be done.

How far the treatment of behaviour disorders and neurotic traits in childhood can be trusted to avert outbreaks of definite mental illness in later life is a disputable matter, but it is fairly certain that by taking advantage of his plasticity and responsiveness, a bent can often be given to the energies of the maladjusted child, which will result in his being socially better adapted and better able to deal with his problems. The more persistent the beneficial influences one can bring to bear on development at this impressionable age, the more valuable the prophylactic effort.

Many of the most effective and urgent measures of mental hygiene that may be recommended to the community as a whole are still largely of a negative kind: what to avoid rather than what to do. This applies particularly in the field of sexual practice and belief where needless fears and harmful education are rife, as with regard to the masturbation of adolescence—a normal and comparatively harmless phase of sexual development.

**TREATMENT OF THE ACTUAL ILLNESS.**—This is almost as varied as aetiology. There are no specific methods of treatment of sure efficacy; nor can treatment safely be limited to one approach, whether physical, psychological or social. There is no valid distinction between palliative and curative therapy: the distinction should be between more efficacious and less efficacious. The nearest approach to a successful causal therapy is attained with those mental disorders which are closely related in time and form of occurrence to some indispensable cause, e.g. a toxic delirium, a reactive depression or anxiety, an interstitial syphilis of the brain. But these are rare conditions if one considers the whole of mental illness. The treatment of general paralysis by artificial fever was not causal, its theory was dubious, its basis quite empirical; yet it was the most important therapeutic advance in psychiatry for a hundred years. One cannot despise any measure that promotes the recovery or well-being of the patient: the giving of drugs, the prevention of suicide, occupational therapy, analysis of motives, induced convulsions, removal into favourable surroundings, hypnosis, insulin, re-education and other means of helping the patient are not to be graded in an arbitrary hierarchy, nor should recovery be called spontaneous—as it often is—if it has occurred after treatment which did not include psycho-analysis or vigorous physical procedures.

Sometimes a patient's condition demands energetic intervention; sometimes it demands restrained symptomatic treatment; sometimes social adjustment is called for; sometimes drugs. Whether the accent in treatment shall fall on the physical or the psychological or the social side will often be less important than care that all the available resources are used. It should not be taken for granted that a diagnosis connotes a method of treatment: e.g. that psycho-analysis is the only thorough treatment for obsessions, while for depression convulsant therapy is the "proper" method.

Nor, to mention another common error, should it be lightly assumed that a heavily tainted family history or other evidence of a strong constitutional factor indicates that treatment is out of the question, a superfluous struggle against fate.

Treatment may be considered as social, psychological and physical. For some types of illness obviously much more stress will fall on one than on another of these, e.g. in hysteria, general paralysis of the insane, epilepsy.

*Social and occupational treatment.*—The first task in social treatment is to decide where the patient is to be looked after. Is he fit to be at home, should he be in a hospital, or in some other environment? The decision as to the need of a psychiatric hospital rests in the first instance on the danger the patient presents to others, or the chance of his committing suicide. These two problems of behaviour were at one time almost the only grounds of admission to a mental hospital, but such questions of "certifiability" need no longer preoccupy the psychiatrist, since voluntary treatment has broadened the scope of the mental hospital and modern conditions made it suitable for many patients who would ordinarily be regarded as "neurotic", rather than "mental", "psychotic" or "insane" (e.g. early cases of general paralysis masquerading as neurasthenia, or obsessionals who fear their own impulses and want to be protected against themselves).

The social decisions in treatment cover much more than merely the mental hospital issue. If the patient's immediate environment contains many disturbing influences, it will be desirable for him to be away from them temporarily at least, so long as this does not entail worse troubles; summary decisions are here impossible. It may be useless to get a woman who is paranoid about her neighbours to move to another district to escape them, unless it is the actual conduct of the neighbours and not the patient's morbid attitude that is provoking her suspicion of them. It requires a close knowledge of the facts as well as wisdom and psychiatric experience to give advice on matters that may wholly alter the course of a patient's life—advice, say, about separating from his wife, giving up his job or emigrating to the Dominions. Many instances of this might be offered. Neurotic patients are often advised to get married, especially if loneliness and sexual needs trouble them, as though marriage were a panacea; such advice by rule of thumb too often makes their condition worse, ruins the life of the person they marry and results in offspring that have to be treated at a child guidance clinic. Weary, depressed patients are often harmfully urged to go to dances and lively seaside resorts where they must try to look happy. Hysterical patients do not benefit by being put among people who are hostile and contemptuous, any more than in an atmosphere of mawkish sympathy and compliance.

In the social treatment of patients indispensable help can be given by trained psychiatric social workers. Their assistance is not restricted to the patient's economic problems. No psychiatric hospital or clinic, whether for outpatients or inpatients, children or adults, can do its work effectively unless a psychiatric social worker is a member of its staff, to provide expert information and advice on all the social aspects of the patient's illness, and to carry out social measures of treatment. Similarly, a non-medical psychologist must be available for help in dealing with educational and vocational problems and the administration of specialised tests.

Occupational treatment is important for all kinds of mental disorder. Where there is acute overt emotional disturbance, rest is at first desirable, as also for confusional and delirious states. In these conditions opportunity for occupation must be gradually offered to the patient as his disorder subsides; steady, simple work is preferable to the restless unsatisfying fickle activity in which he would often engage, if left to himself. The less acute any mental disturbance, the more necessary is it that occupation should be urged upon the patient, and that it should be disciplined and congenial. This applies equally to gross psychoses and minor affections of the neurotic sort. Allowance must be made for the patient's bent, his symptoms and personality, and especially his more or less conscious reasons for working and not

working; hence there will be much diversity in the conditions of his occupation, whether it be therapeutically contrived in a hospital, offered at a Rehabilitation Unit or sought out as remunerative work in the open market. Mental health cannot be permanently retained unless one does some satisfying work; often it cannot be recovered unless one does. Work is not satisfying, in the long run, if it is done mainly as a diversion to fill in time.

*Psychological treatment.*—There is no form of treatment which has not a psychological aspect and result. The term psychological treatment or its synonym "psychotherapy" is, however, conventionally limited to those forms which depend upon direct and personal relationship between the patient and the physician. They have been given separate names, and divided into schools and techniques. Stress may be laid upon the prestige of the physician (as in hypnosis), the patient's attachment to him, in all its complicated phases ("transference"), the trained understanding and thoroughness with which he clears up the patient's problems (persuasion, re-education, distributive analysis), or on his qualities of personality—enthusiasm, energy, warmth, candour, wisdom. In so far as psychological treatment is necessarily based on a personal relationship it cannot be made a routine except in its non-essentials: whatever rules the psychiatrist follows or whatever the training he has undergone, he himself is more important than his method in benefiting the patient. To that great extent psychotherapy is not a scientific procedure. That is not to say that method and training are of no consequence—far from it—but only that they are devices whereby the influence of one human being upon another's mind and conduct can be turned to the best medical ends and the dangers inherent in such a relationship minimised.

The more specialised, intricate or esoteric the method, the less suitable is it to be used by any but the expert. It is not proposed here to detail the many kinds of technique that have been employed. The general rules that must be followed in any psychotherapy are:

1. To regard the removal of symptoms as a good thing, but the maintenance of normal social adaptation as far better. It is bad to get rid of one symptom only to see it replaced by another, but much worse to get rid of all symptoms only to see the patient at the end of treatment a dependent and introspective hypochondriac of the mind, a social invalid.

2. To seek for the psychological causes of the patient's illness only to the extent that the patient's well-being demands, which is often far short of what one's own interest and psychological curiosity would demand.

3. To consider carefully whether any shock to the patient, any aggravation one produces in his illness even temporarily, may be a sign of bad treatment.

4. To be satisfied with the patient's recovery, and not to aim at his promotion to a state of ideal mental health and self-understanding. It is better that treatment should be quick and effective than drawn out to meet theoretical standards.

5. To understand the development of the patient's illness, and to interpret it both to him and to oneself, in terms of real experience rather than of hypothetical forces.

6. To treat the patient without allowing one's own emotions to be more concerned in the course and outcome of the treatment than is usual in the treatment of a physical illness.

7. To aim at harmonising the patient's mental life by giving his ill-managed energies fitter material to work at, and release from the burdens laid on them by past experience.

It is impossible to describe in general terms what the psychotherapist does, otherwise than by metaphor or analogy: he promotes the ventilation and desensitisation of emotional disturbances; he elucidates latent or obvious muddles, disentangles conflicting tendencies, giving them new incentives and a different direction; and so

guides the patient through the maze of his life's experience, as recalled in memory, that he is then better fitted for dealing with current experience, knows himself better and has somewhat purged himself of past harms. All "analytic" methods review the patient's life as he recalls it under special conditions, e.g. of free association, hypnosis, biographical scheme, etc. They stop at different points, some aiming at emotional clearance by abreaction, some at a redirection and liberation of the instinctual bases of character, while others remain content with an educational achievement.

Whether psychotherapy, in the above sense, is to be applied will depend on the following factors: the patient should be willing to co-operate in the treatment; free from such hindering disabilities as, say, deafness; able to give the necessary time; of at any rate average intelligence; still capable of modification (as he would not be in old age, or with very long-standing and indurated habits of faulty reaction, or with organic cerebral disease); and, finally, endowed with a considerable residue of normal mental functions with which one may work. The more profound his aberrations, as in schizophrenia, or the more extreme his emotional disturbance, as in agitated melancholia, the less is he fit for psychological treatment of this individual and specialised kind. Psychological treatment, however, in the literal and larger sense of the words, is essential for every variety or stage of mental illness, and every degree of co-operativeness or intelligence. It is a wide notion, including all that may ease or reassure the patient, bring him to a better relationship to those around him and with himself, and protect him from being distressed by the ignorance, lack of tact, or thoughtlessness of others. It is as much negative as positive. One must avoid arguing with the patient, telling him lies "for his own good" or to avoid unpleasant scenes, cajoling him, making promises that will not be kept, threatening or punishing him, jesting at his expense, losing one's patience with him, assuming he is indifferent to what goes on because he looks indifferent, provoking him by petty supervision or frequent rebukes; one should not assume that he is quite irresponsible or quite responsible, nor talk theory to him, nor get on a false footing through ready assent to his delusions and his point of view. The physician and the rest of those who are in contact with the patient must do certain positive things: make due allowance for his disorder influencing his conduct, use their understanding of the psychological happenings without saying so, take advantage of every opportunity created by other methods of treatment. When occupation, narcosis, hydrotherapy, a course of insulin, massage, a physical illness or other happenings bring him more closely into contact with nurses and physicians there are chances of unobtrusive psychological treatment in the wide sense.

Of late much effort has been put into treating patients, not as individuals, but as members of a group. Though less economical of time and labour than had been hoped, this has the advantage of utilising for therapeutic purposes the influence that patients have on one another. Many devices have been employed, from social club meetings to "psycho-drama"—plays that originate with the patients and touch on their conflicts, and are followed by a group discussion. The procedures are still experimental, and have not made individual treatment superfluous.

*Physical treatment.*—"Mechanical restraint" and violence are now foreign to the treatment of insanity; the patient may be unrestrained and violent, but his treatment may not. It is still necessary, however, to restrain a patient who is bent on harming himself or others, and physical force may be the only way of doing so, or of giving a patient by tube enough food to keep him alive when he abjures the natural way of eating. But force must always be a last resort; and chemical substitutes for it seem only a little less of an evil. Drugs have their place in the treatment of all kinds of mental disorder, but their use easily turns to abuse. Whether one is giving morphine and hyoscine in an emergency to an acutely excited catatonic, or prescribing aspirin for a mild hysteric, the chief danger which must be borne in mind is not over-

dosage, habituation or suicidal misuse, but the habit of stupefying or satisfying a patient with drugs when other means might be taken, better suited to his condition. Sedative drugs should not be a short cut; neither should they be eschewed. They should be given when other measures will not serve, as for some obstinate form of insomnia, anxiety, agitation and restlessness, or when their use obviates greater troubles, e.g. the pulling of bandages from an operation wound. The symptoms of intoxication must be watched for with more than usual vigilance when bromide is being given, because if unrecognised as such they may lead to certification—for an avoidable drug-made psychosis. Continuous narcosis for several days with the patient sleeping through 18 or more of the 24 hours, is sometimes efficacious in abbreviating an acute attack of mental illness or giving complete rest to an exhausted, very anxious person; it is not without risk, except in skilled hands.

There are other drugs to which the above cautions scarcely apply, e.g. endocrine preparations, remedies specific and otherwise for the physical basis of "organic psychoses" (e.g. arsenical treatment for syphilis of the central nervous system), and aperients. Insulin for promoting hunger, calcium for those with hysterical hyper-ventilation fits, amphetamine (Benzedrine) and acetylcholine for anxiety, and a number of substances—from nitrous oxide to amylobarbitone (Amytal)—that relieve catatonic stupor, or facilitate psychological enquiry and treatment, have all been found useful on occasion. Recently hypothermia induced by chlorpromazine (Largactil) has been employed, but its value is highly doubtful. The same may be said of malononitrile.

Three methods of physical treatment have been introduced and widely employed since 1935, namely: (1) insulin in large doses to produce hypoglycæmic coma repeatedly; (2) convulsant drugs and, latterly, electrical stimulation of the brain, to bring about fits and (3) surgical incision of both frontal lobes—leucotomy—to sever the connection of the anterior portions with the thalamus. Although the former procedures, and their many modifications, are often referred to by the single ill-chosen term "shock therapy", they have little more in common than that they are crude empirical methods of altering mental disorder for the better, their *modus operandi* being still a matter of conjecture. Since the insulin method demands skill and experience, if considerable risk to life is to be avoided, it has not been so much used as convulsant treatment. Its field of application is schizophrenia, especially the early acute forms with good prognosis. Convulsant treatment is now given almost always by the electrical method. Though first devised for schizophrenia, it has limited success there except in the acute stuporose forms and those associated with an affective syndrome. Its efficacy in involutional and some other affective disorders is, however, striking. It terminates obstinate melancholias and abbreviates attacks of depression which would otherwise take many months to clear up.

Frontal leucotomy has a more insecure place as yet than the other two methods. It has been, or should be, restricted to patients who seem proof against other forms of treatment, e.g. those with chronic agitated depression, long-standing schizophrenia accompanied by violent outbursts, or intractable obsessional disorder. The proportion of deaths in a fairly large collection of cases has been between 3 and 4 per cent.; of recoveries (obviously dependent on the patients selected for operation), about 25 per cent.; another 40 per cent. are said to be clinically much improved; about 65 per cent. of those operated on do not improve sufficiently to leave a psychiatric hospital. The procedure does not reduce formal intelligence, but blunts spontaneity and control, and may impair judgement and foresight; it may lead to epilepsy (in from 4 to 8 per cent. of cases), or urinary incontinence. Some of the successes attained by the operation in apparently hopeless cases indicate that its uncertainty and crudity do not put it out of court; modifications in the site and extent of the cut are still being made, with promising results.

The three forms of intervention described stand or fall, not by appeals to general principles or evidence that they are rational and safe, but by proof of their value in

alleviating specific types of mental illness. They evoked a somewhat uncritical enthusiasm and hopefulness in some who had previously been given to ill-informed nihilism about the prospects of any treatment; consequently the mistaken notion has gained ground that before the advent of these methods patients who got well must have done so "spontaneously", and that unless a mentally ill person has had "shock therapy" or "psychotherapy" he cannot be said to have had any treatment at all.

Exercise or massage and hydrotherapy are beneficial as much for their psychological as for their physiological results; the latter, however, are not negligible, as may be seen in the effect on an excited or an anxious patient of a continuous bath at body temperature. The chief importance of diet lies in the frequent refusal of food by patients depressive, hysterical, stuporose, paranoid, hypochondriacal or over-active. Feeding by the nasal or œsophageal tube is a necessity in many such instances, after every other method has failed. Rarely a special diet is called for, as in the symptomatic psychoses of diabetes, pernicious anemia or pellagra, and also for some temporary disabilities of the alimentary tract. As a rule, however, such dietetic régime, and indeed all physical treatment of localised psychogenic disturbances of function in a bodily system, is an expedient rather than a settled and adequate mode of treatment. Many patients with a visceral neurosis (e.g. "effort syndrome"), a hypochondriacal preoccupation, a hysterical anomaly, or a somatic delusion are greatly harmed by the prolonged physical investigation and treatment they receive: it confirms the symptom, localises it all the more and brings fresh ones in its train. Sometimes one has no choice; a progressive hysterical contracture, a dermatitis artefacta, a sore infected by constant picking, a tooth loosened by obsessional knocking at it demand treatment.

The caveat against lightly resorting to physical treatment of psychogenic anomalies is especially applicable to operative surgery, e.g. "cleaning up the septic foci".

## CLASSIFICATION

The ideal classification would be on a uniform basis, according to the nature of disordered physical and psychological function, or according to innate and external causes. Since we do not know enough to do this, a mixed ætiological, functional and clinical grouping is used. It is obviously provisional. The chief division is between those mental changes accompanying distinctive somatic disorder and those for which no such physical relationship has been demonstrated. The former are called symptomatic, or organic; the latter constitutional or functional. It is needless to illustrate the point that everything found in the latter may be seen also in the former. The reverse of this is not true, because there are some symptoms—due to the loss or damage of essential tissues, especially in the central nervous system—which can only occur when the material substrate is grossly damaged.

Although the "functional" group is made up of those conditions for which no distinctive somatic disorder can be found responsible, it by no means follows that their causes or basis are therefore purely psychological. Theoretically, such a belief is untenable, since physiological and psychological are only different facets of the same phenomena; and as a matter of observation certain physical disturbances so regularly accompany these disorders, and a physical configuration may be so linked with them, that there is small doubt that eventually the somatic disturbance of function in them will be well enough worked out for the terms "organic" and "functional" to lapse, and only the crudity or transience of the physiological changes remain as a point of difference.

The first or toxic-organic group is large, the chief syndromes in it being neurasthenia, confusion, and delirium and dementia. Such phenomena as apraxia, aphasia, agnosia, amnesia and hallucinosis are fairly frequent in this group.

The second group, comprising three-fourths of the recognisable mental illnesses, includes the insanities or psychoses, and those anomalies, outwardly less alien to the normal mind, commonly called "neuroses". The distinction between neuroses and psychoses is at times convenient, but without substance. To argue whether a dubious case is neurotic or psychotic is like arguing whether a man of medium size is thin or fat: he is both and neither. A genuine decision as to ætiology, prognosis or treatment turns not on whether a case is regarded as neurotic or psychotic, but on more solid findings. Since such words die hard, the best use of them is to term a patient with mental disorder "neurotic" if he has fair insight into his illness, is co-operative and unlikely to need care in an institution, and to term him "psychotic" if the contrary is the case.

The toxic-organic group is divided into diseases located in the nervous system and those affecting it indirectly, as uræmia or lead poisoning may. Some are toxic, *e.g.* delirium tremens; some degenerative (*senile psychoses*); some inflammatory, *e.g.* encephalitis lethargica; some plainly hereditary, *e.g.* Huntington's chorea or "primary" mental defect; and some privative, *e.g.* pellagra or myxædema.

The "functional" conditions are arranged according to whether emotional disturbance is evident and predominant (affective disorder), or whether there is profound derangement of thought, feeling and contact with the real world (schizophrenia), morbid false beliefs have become fixed without intellectual or emotional deterioration (paranoia), repetitive and seemingly irrelevant phenomena hamper mental activity (obsessional), signs of physical or mental ill-health, especially dissociation, readily appear when an unpleasant situation may thereby be escaped from (hysteria).

As will be seen in the special sections, the personality of the patient may also be a criterion of these groupings, with the proviso mentioned earlier that illness does not only occur in those with the appropriate psychopathic anomaly of personality, nor does the latter by any means regularly issue in definite symptoms. Unless, however, psychiatry takes account of the psychopathic personality, even when not accompanied by symptoms of illness, it cannot study delinquency, disorders of behaviour in children, sexual perversions and other anomalies which touch very closely on psychiatric problems in the stricter sense.

The following is the classification used here; it is much less detailed than that of the International Statistical Classification, to which, however, it can readily be assimilated:

### Organic Disorders:

#### Degenerative and Hereditary Brain Disease.

(*Senile dementia, cerebral arterial disease and hypertension, Huntington's chorea.*)

#### Syphilis of Central Nervous System.

#### Other Cerebral Diseases.

(*Lethargic encephalitis, Sydenham's chorea, disseminated sclerosis, cerebral tumour, cerebral trauma, epilepsy, etc.*)

#### Intoxications.

(*Alcohol, morphine, cocaine, bromide, etc.*)

#### Infections and Exhaustive Disorders.

(*Infectious toxæmias, hæmorrhage, etc.*)

#### Metabolic, Endocrine and Visceral Disorders.

(*Diabetes, pernicious anæmia, pellagra, exophthalmic goitre, myxædema, tetany, pituitary diseases, sexual epochs, cardiac disease, uræmia, etc.*)

**Affective Disorder.**

Excitement.

Depression.

Anxiety.

Schizophrenia.

Paranoia.

Hysteria.

Obsessional Disorder.

Psychopathic Personality.

Mental Deficiency.

Mental deficiency, instead of being treated as quite separate from the other classes, might logically be distributed among them. Most of the feeble-minded are probably "sub-cultural", that is, they represent the lower end of a curve of normal distribution of intelligence throughout the whole population, intelligence being here comparable with height. But just as there are dwarfs whose brevity is not a physiological attribute but the consequence of disease, so there are many defectives (almost all idiots fall into this class) whose low intelligence is the result of demonstrable interference with cerebral development, sometimes from hereditary and sometimes from environmental causes. Members of the sub-cultural group, which is by far the more numerous, have it in common with people of psychopathic personality that they are not conspicuously different from the average population, they are not ill, and their troubles are partly due to and manifest in their social relationships, not least during childhood. The pathological groups could be systematically classified according to the disease responsible for their maldevelopment; they differ from the other organic forms of mental disorder only in the age at which the damage has been done. Congenital syphilis, cretinism, cerebral trauma, encephalitis, epiloia, cerebro-macular degeneration, microcephaly, gargoylism, hydrocephalus, epilepsy, Huntington's chorea, congenital diplegia; a long list can be made of the diseases which will interfere with normal cerebral and intellectual growth, if they can begin to act early enough. Custom and convenience, however, are arguments in favour of keeping all mental deficiency in a class by itself.

The above are great clinical groupings, types of morbid reaction, which are as near to a valid and useful classification as we can get at present. There are subordinate symptom-complexes or syndromes, which are likewise innate and preformed, and likewise evoked by circumstances, but which are not limited to any one of the major groupings—they are the web that runs across the psychiatric pattern. The most important of these are depersonalisation, hypochondria, twilight states, stupor and other disorders of motility, and spasmodic attacks and seizures of different kinds. Between symptoms (classified on a psychopathological basis) and the main groupings which best serve clinical purposes, these symptom-complexes have an intermediate place, comparable say, to that of mononuclear leucocytosis or coma in general medicine.

**ORGANIC DISORDERS****GENERAL DESCRIPTION OF TYPES**

The varieties of form and course in organic psychosis are essentially few and simple, in contrast to the causes, which are numerous. In other words, there is no support for the expectation that to each physical disease there corresponds a characteristic mental disorder. It is not possible in an organic psychosis by study of the

mental picture alone to infer its physical cause; for that the methods of somatic medicine are needed. Many different poisons and lesions may produce the same effect on the mental state. Differences depend on the degree and duration of the physical damage and its site, which may determine neurological and other symptoms of a typical kind; *e.g.* in G.P.I. or encephalitis lethargica.

They are the least constitutional of all mental affections, yet even in them constitutional factors are far from negligible. It is due to such factors that one man will show a psychosis with physical illness that in another would lead to no such mental upset, and that one patient responds with a manic extravagance to the cerebral disease that makes another patient depressed. Moreover, hereditary factors can be of great importance in these organic affections, as may be seen in amaurotic idiocy or Huntington's chorea.

The few syndromes commonly met with here, though they are not restricted to organic disease, must be described before seeing how particular diseases colour them and determine their course and treatment. In organic syndromes, a diminution in mental capacity is the central finding. To some extent these syndromes may occur also in patients in whom no structural damage can be found, as might be expected seeing that the available patterns of structure and function are in all cases much the same.

(1) **NEURASTHENIA.**—This term has been over-used and ill-used, like most of the more palatable diagnoses (*cf.* anxiety neurosis), but it need not therefore be discarded now. It denotes a form of irritable, hypersensitive weakness and depression that is not uncommon after infections, exhausting experiences (*e.g.* hunger, lactation, insomnia, worry, hemorrhage), cranial injuries and chronic poisoning (*e.g.* with alcohol or coffee). It is true that a clinical picture indistinguishable from it frequently arises where physical causes are unlikely and emotional causes are obvious: this clinical finding has the same significance as the fact that the anxiety of exophthalmic goitre is like psychogenic anxiety. Just as the anxiety of exophthalmic goitre or constant fear can pass into delirium, so can physiogenic neurasthenia be aggravated until it becomes plain dementia.

The symptoms are partly somatic—active deep reflexes, increased sensory irritability, feelings of pressure on the head and pains in the muscles and elsewhere, giddiness, vasomotor lability, delayed peristalsis and feelings of fullness in the abdomen, diminished libido, slight clumsiness, and tremor of the muscles of the face, tongue and hands. On the more psychological side, there are feelings of languor, and incapacity to concentrate on any mental work, doubts as to the accuracy of memory, loss of interest, slight depersonalisation, irritability and tenseness, lessened control of emotion, and perhaps slight paranoid, obsessional or hypochondriac trends. This general condition is, when physiogenic, less influenced by a change in mood than would be the case with psychogenic neurasthenia, and the patient is better able to control his motor unrest than his features, which are expressive of his agitation. The chief reliance, however, must be put on the history and physical findings for telling whether the neurasthenia is physiogenic or not; psychological causes which seem adequate to explain the illness may be deceptive.

The course of neurasthenia is towards recovery unless the noxa continues to act; where the noxa persists, extreme chronicity can result. Sometimes an original physical noxa ceases to act, but meanwhile other emotional ones have entered the field, *e.g.* unemployment, domestic fears and frustrations, and so the illness drags on. Treatment depends on assessment of the causes and the possibility of removing them.

(2) **DELIRIUM.**—Delirium, most familiar in fevers, can also be produced by drugs and other causes of acute cerebral disturbance: severe affective disturbance also may be accompanied by delirium. Its characteristics are general malaise, restlessness, irritability and sensitiveness to external stimuli, headache, anxiety and troubled sleep or insomnia. Mild forms of this are met with in so transient an affection as cold in the head. Severe forms are marked by illusions and hallucinations of all the special

senses, especially vision. Anxiety often becomes extreme, and the patient is terrified of his fantastic visions. Thought becomes as chaotic and fleeting as in dreams, activity is incessant and past experiences of daily life are revived, as in the occupational delirium of alcoholics. Attention is weakened, and orientation in time and space much impaired. There are striking variations in the severity of the condition in the same patient: it becomes worse in the evening or when the patient has hardly any external stimuli to keep him in touch (cf. delirium at night and after a cataract operation). The extent to which consciousness is clouded usually corresponds to the amount of perceptual and affective disturbance. Auditory hallucinations occur with clearer consciousness, visual ones very profusely with a clouded mind. The auditory hallucinations are commonly of an elementary, undifferentiated kind—not voices. Vestibular hallucinations may occur, e.g. of floating in the air. Distressing and incoherent ideas pursue each other—ideas of being torn to pieces, burnt, poisoned, buried alive and so on; also ideas of grandeur.

Closely akin to delirium, and indeed shading into it, is the state of clouded consciousness (or confusion) in which thought is very incoherent, but the patient is more eager to get in touch with his environment than in typical delirium. If consciousness is not too grossly clouded, the patient is perplexed and troubled by the disordered perceptions through which alone he can learn what is going on about him. The picture may be indistinguishable from that seen in some forms of manic excitement and in some catatonic states. Differentiation rests, not on the immediate psychiatric symptoms, but on the history and discoverable causes of the illness. The same is true of *acute hallucinosis* in which orientation and grasp are very little impaired, but auditory hallucinations—especially threatening sounds and voices—abound, and there is a tendency to the formation of delusions on the basis of these and other perceptual disturbances. The name "*twilight state*" is applied to another syndrome in which consciousness is changed chiefly because of some powerful affective influence; anger or fear may so overwhelm psychic life that the patient cannot grasp his surroundings, his thinking is interrupted and slow (except where it falls in tune with the affective disturbance), and his motor behaviour is in keeping with his mood. It is as often of psychogenic as of organic origin—one can hardly, for example, by direct observation tell an epileptic twilight state from an hysterical one. Like delirium and the other conditions just mentioned, it is prone to subside and to be followed by amnesia for what happened during it: where there is some recollection, it may be associated with a conviction that the hallucinations and other morbid phenomena were real external happenings.

(3) **DEMENTIA.**—Of all gross encephalopathic syndromes this is the gravest and most typical. It corresponds to a diffuse cerebral disease, and is made up of intellectual impairment and lessened control of emotion. Its form depends so much on the stage of the patient's development at which it occurs, that it is customary to consider as dementia only those cases in which the cerebral damage has occurred in later childhood, adolescence or adult life, and to regard earlier cases, e.g. cretins, as showing mental deficiency or arrest of development. The distinction is rather artificial, at whatever age it be made. For convenience, only the adult form will be described here. The order in which functions are impaired corresponds to Hughlings Jackson's principle of dissolution: thus, recently acquired memories are soonest lost. There is intellectual weakness—the patient cannot reason, grasp and remember as he could, his attention is less concentrated and sharp, his ideas are fewer, he cannot take in anything complicated or be sure about time and place, he loses himself. His emotions are likewise affected—he weeps over trifles in spite of efforts to control himself, his feelings are shallow and transient, he may be foolishly euphoric, or may burst into anger whenever he cannot get his own way. There are wide variations in the severity of the condition, and its symptoms may be much influenced by the local incidence of the pathological changes in the brain. The extent to which various cerebral func-

tions are impaired may differ widely in the same patient: a man who seems hopelessly demented may be able to play a good game of chess, while another in whom it is hard to demonstrate any intellectual impairment may micturate into his shoes or do something equally stupid and inappropriate; unexpected sexual misdemeanours are not uncommon in demented persons who do not as yet show gross intellectual damage.

Psychological tests have been increasingly used in dementia. Although they are untrustworthy for diagnostic purposes, they can be of value in measuring the degree and progress of the impairment. The most convenient method is that devised by Babcock in which the discrepancy between vocabulary score, which is often well preserved in dementia, and performance on non-verbal tasks is assessed. More elaborate differentiation by means of a wide variety of tests is still in the experimental stage.

Closely connected with dementia are the *amnesic syndromes*, known by the name of Korsakoff. Here the *memory disturbance is in the forefront*. The incapacity to receive, store and reproduce experience is remedied, as it were, by lying, *i.e.* the patient *confabulates to fill up the gaps in his memory*. These patients are often ready to adopt suggestions, so that one can lead them to tell absurd tales about their recent movements, *e.g.* that they were yesterday in Greenland to see some polar bears. They do not show an intellectual damage or incapacity to deal with ideas that is at all comparable in degree to their memory disorder, but they are always out in their appreciation of time-relationships, especially where the present is concerned. At first blush they often seem to be behaving like mentally healthy people, but one presently discovers that their memory is much impaired, their orientation as to space, time and personal identity correspondingly poor, and their interest and general mood duller than is normal. The disorder of memory is never, as in dementia, a general weakness reaching back even to childhood.

The Korsakoff syndrome is most often seen in alcoholics, in whom it was first described associated with polyneuritis, but it also occurs in a great variety of organic disorders, *e.g.* intoxication with lead, carbon monoxide and other poisons, uræmia, vitamin B<sub>1</sub> deficiency, cranial trauma, cerebral syphilis and arteriosclerosis—apoplexy may precede it and the amnesic syndrome be thus complicated by aphasia. That it should sometimes follow on delirium is not surprising, since in delirium the same memory disturbance is present, but covered up by the concomitant excitement, disturbance of consciousness and hallucinations. Whether a Korsakoff syndrome will clear up depends on the cerebral damage which produces it; the alcoholic form occasionally does so eventually in uncomplicated and treated cases.

Mental deficiency in some of its forms is a special instance of cerebral impairment, as is dementia. It is considered, for the sake of convenience and tradition, in a separate section (see p. 1682).

## DEGENERATIVE AND HEREDITARY BRAIN DISEASE

There is a group of disorders occurring in late middle life and old age, which are clinically and even pathologically near to one another. At the one end of the scale is senile dementia, at the other climacteric anxiety and depression. It includes Pick's presenile dementia, Alzheimer's disease, cerebral arterial disease and arterial hypertension.

The mental disorders of age have displaced schizophrenia and manic-depressive psychosis from their position as the mental disorders of highest incidence. When first admission rates per 100,000 of the corresponding population have been computed either for senile psychoses or for psychoses with cerebral arteriosclerosis, a higher figure has been obtained than for the incidence of all other psychoses

combined; the chances of becoming thus mentally ill, therefore, are higher in the elderly population than are the chances of developing all other mental illness in any age-group of the population. If present trends continue, the number of persons over 45 years of age admitted to English mental hospitals in their first attack of insanity will by 1971 approximate to the total number of first admissions of people of all ages in 1937; more than a third of these admissions will be of people over the age of 65. It is not extravagant to say that nowadays insanity is mainly a disease of old age.

### 1. SENILE AND PRESENILE DEMENTIA

**Ætiology.**—Constitutional factors are obviously the most important. A tendency to become dotards may be evident in successive generations of a family; heredity is held responsible for the wide differences in mental health among elderly people. The symptoms of senile psychosis may not be revealed until the patient is exposed to some sudden stress—the death of his wife, the need to move house, the loss of his occupation, some new set of circumstances. Social factors are of great importance. Senile psychoses are more common in people with lifelong nervous symptoms or psychopathic personality.

**Pathology.**—**PHYSICAL.**—The tissues show the general signs of age, *i.e.* a diffuse atrophy, which makes the convolutions narrower and the weight of the brain less. The nerve cells and fibres are fewer, while the mesodermal and neuroglial tissues are increased; fatty pigment accumulates. There are also, however, in senile dementia striking histological features in the grey matter, especially of the cortex, namely, thickening of the neurofibrils, which are characteristically twisted and aggregated, and there are remarkable plaques, seldom seen except in this condition. The main change is probably in the brain colloids so that condensation and coagulation take place; the plaques and thickened neurofibrils are secondary to this. There is no close correspondence between the kind or extent of the tissue changes and the mental state. Plaques and neurofibrils can occur also in the brains of mentally healthy old people.

**PSYCHOLOGICAL.**—The previous tendencies of the patients may greatly colour the symptoms. Obscure somatic preoccupations and disturbances in time appreciation lead often to fantastic delusions about eternity and what is happening in their body.

**Symptoms.**—Memory is poor for recent events; the extent of the damage may increase until only the recollections of childhood and early adult life remain. People and places are falsely identified with those once familiar, and transient pseudo-memories are invented. Events with a strong affective tone, especially if unpleasant, are remembered better. The memory of the remote past is not entirely spared; even matters of personal identity may at last be forgotten. Grasp and judgement, the capacity to follow a train of thought and to eliminate the irrelevant are faulty. Obstinacy and perseverance go with a rigid adherence to old habits. Prolix and garrulous, the patient does not recognise how little interest there is for others in his repetitive and ill-arranged talk. He may partly cover its emptiness with long and sounding sentences; on the other hand, some patients become monosyllabic, because of their failure to find words to express themselves, and others again will use a word loosely associated with the one they are vainly seeking, or will quite seriously give a punning meaning to a word, and even act accordingly (*e.g.* whistling because "You said I could whistle for my money").

There is a narrow range of interests, in which food, possessions and bodily well-being are prominent. Grotesque hypochondriacal delusions are common. Patients hoard rubbish and are angry if interfered with in this. On the whole, however, their affective responses are greatly reduced; they meet calamities with composure, partly due to their failure to grasp what has happened. Now and then they show depression and resentment at a slight, and may bear a grudge long after. Their activities are

sometimes considerable, on the lines of determined rummaging and collecting; in others a dull inactivity is all. They become dirty and unable to look after themselves. This applies as much to those who are excited and active as to the inert. The former may fight against being fed and washed, and it is not possible to get them to understand what is being done. Delirium and confusional states are prone to occur at night, accompanied by fear and bewilderment. Sleep is bad, and often the patients busy themselves about the place all night long.

Legal difficulties arise through the heightened readiness to accept some suggestions (as in the matter of making a will, or giving away property), the poorer judgement and the lessened capacity to control sexual desire which is sometimes seen in the early stages. Hoarding may lead to petty thieving. Occasionally the patient sets fire to the house during his nocturnal prowlings.

The symptoms need not be obvious. Often the illness has so slowly developed that no one can say when it first passed beyond what is normal in old age. An apparent change of character—a kindly man becoming selfish, a respectable churchwarden assailing little girls sexually—may usher it in; this is not so much a change in character as a release of primitive trends, hitherto controlled. The psychosis may take various forms—depressive, manic and paranoid. In the *depressive* variety there is seldom retardation, the affect is rather empty, the patient is irritable and hysterical symptoms may be commingled with hypochondriacal ones. Ideas of poverty, wickedness and disease are often grotesque in their exaggeration—the patient's urine drowns the whole world, his body is an undying shell of corruption, he is as tiny as a baby—and are monotonously reiterated. The *manic* variety is rarer: pointless activity and a diarrhoea of words, with silly boasting, may be accompanied by a disturbance of memory, giving a total picture of the Korsakoff type: it is sometimes called "presbyophrenia". Many of these patients have always been of hypomanic temperament; their illness may be only slightly progressive and not so severe as to call for hospital care. The *paranoid* variety is especially likely to occur in people who have always been of a suspicious turn of mind. They hide things because they feel surrounded by thieves, and then forget where they have hidden them; their failing senses, especially of hearing, feed their distrust and they project their awareness of sexual impotence or waning intellect. Hallucinations and delusions are mingled—gases are pumped into their room, their food is poisoned, people throw bombs at the house by night, greedy heirs are doing them out of their possessions. Some of these patients barricade themselves against their enemies or call in the police. Whereas the depressive and manic forms are commoner in people with corresponding heredity, this paranoid form is genetically often connected with schizophrenia, though the distinction between the three varieties is not a sharp or important one. The name "involutional paranoia" has been given to the chronic delusional condition of this type that may develop in single women between the ages of 40 and 52.

Bodily symptoms are those of old age, especially in the central nervous system, where it leads to a slow, careful gait, with short steps and legs wide apart, apraxia and poor co-ordination, tremulous rather whining utterance, small sluggish pupils and occasionally epileptic seizures. The disorder of movement is conspicuous in the handwriting—pointed, small or erratic in size, and sometimes jerky and tremulous.

The conditions known by the names of Pick and Alzheimer are to be regarded as atypical senile or presenile psychoses.

Pick's dementia consists pathologically of a circumscribed cerebral atrophy, mostly in the frontal or the temporal lobe, or in both; the motor area, however, is seldom affected, nor are Wernicke's zone and the transverse temporal convolutions; other areas of the brain, especially the parietal, may be involved. Histologically, the ganglion cells are swollen and contain argentophil globules. There is a hereditary determinant. It is almost twice as frequent in women as in men—the opposite of what has been found to hold for cerebral arteriosclerosis. The onset, which is

and sclerosis (in which cavities and scars of glial, astrocyte and mesodermal tissue take the place of the necrotic cells) (see also p. 1443). The cortex on the convexity of the brain may show microscopic areas of perivascular gliosis, but no softening. It is not yet possible to correlate the mental and the cerebral changes in these psychoses, except for the focal lesions.

**Symptoms.**—Since "essential" hypertension often precedes definite vascular disease and itself produces mental symptoms, a description of these symptoms serves also to describe the earlier stage of cerebral arterial degeneration. Along with headache, giddiness, tinnitus, faintness and insomnia, there may be disturbance of speech and writing—the former becoming slow and at times indistinct—and transient pareses and apraxia. Certain traits of personality may be intensified: the patient becomes irritable, egotistic, moody and easily tired, his conversation lumbers along where once it moved easily: he is depressed or paranoid; but there may be wide variation in the intensity of these changes, which are by no means always found. Brief phases of disturbed consciousness, lasting up to 3 weeks, may suddenly occur either in a form very like the "absences" of the epileptic, or as twilight states with hallucinations, ecstasy, incoherence, disturbed motility and agitation.

After this stage of neurasthenia and episodic disturbances, the patient with cerebral vascular disease may begin to have trouble in finding words: he perseverates a little, and is at a loss when anything unusual is required of him. His depression and hypochondriacal worries increase, he is distressed by his own slowness and failures, and may attempt to kill himself. Emotional control falls off so that he weeps and storms when he would rather be calm. Nihilistic ideas may abound—his bowels have not been opened for 6 months, his trunk is a hollow cavity. Nocturnal delirium is frequent. Aphasia and apraxia are commonest after a focal complication.

The most important feature is the way the patient continues to look normal and sensible when already mildly demented. Sometimes transfer to the strange surroundings of hospital is too much for the hitherto well-preserved outward normality, and the patient goes to pieces, as he also may if he has to give up his usual work or move house.

**Diagnosis.**—Because a patient has generalised arterial disease, it does not follow that any psychiatric symptoms he may show are due to the cerebral vessels being thus affected. Unless there are definite focal symptoms, or evidence of dementia, it is unsafe to hold the cerebral arteries responsible and to give a prognosis based on this. There is no known means of distinguishing many benign "neurasthenic depressions" and involutional hypochondrias from those due to disease of the cerebral vessels. If there has not been any history of such tendencies until an attack at the age of 60 odd, the probability that it is an organic vascular disease is much higher. The distinction is all the more difficult because so many unstable persons develop arterial disease in later life; especially those prone to anxiety and other affective disorders. *Neurological findings (see p. 1443) may be decisive in a doubtful case. The condition of the retinal arteries is not a reliable guide.*

**Course and Prognosis.**—In definite cases of cerebral arterial disease with mental disorder the prognosis is necessarily bad, though the mental symptoms may only progress slowly, and the patient live another 10 or 20 years. Much will depend on such sudden accidents as thrombosis or hæmorrhage. An episodic confusional state, perhaps even one produced by drugs, may suggest a needlessly gloomy prognosis. In cases of "essential" hypertension, the course of the mental illness is dependent on the general disturbance, and is often quite favourable. Symptoms that are apparently hysterical, occurring for the first time in middle life, are of bad omen.

**Treatment.**—Besides the general medical care of such patients, not a little can be achieved by psychiatric methods. In the early stages, where there is much anxiety and depression, too energetic physical investigation and treatment may do harm: reassurance and sedation can do much good. The less said to the patients about

gradual, can be at any age from 40 onwards, but is usually between 50 and 60. Symptoms depend on the localisation of the atrophy. Memory and affect are not impaired till late; they are preserved at a stage in which the patient behaves stupidly—stealing, lying or otherwise making a fool of himself. Spontaneous attention is poor; at first moody, the patient becomes dull and unresponsive; judgement deteriorates and initiative fails. Stereotypies, echolalia and repetition of empty phrases, monotonous talking and laughing or singing, and outbursts of bellowing or whining appear in the later stages. There may be aphasia. Diagnosis is difficult during life; it may be assisted by an encephalogram showing the shrinkage of cerebral tissue from atrophy or by biopsy. The condition may last from 2 to 12 years.

In *Alzheimer's disease* the senile plaques and neurofibril changes are very numerous. The onset may be between 40 and 60. Women predominate. Indefinite premonitory symptoms (headache, irritability, forgetfulness) are quickly followed by progressive dementia; aphasia and apraxia are prominent, though less coarse and sudden than in cerebral arteriosclerosis. In the earlier stages the patients are in fair contact with their environment, and look as though they grasp much more than they actually can. Their deficiencies are shown up in writing and talking. They may be restless and depressed. As the disease advances they are less open to affective influences: they sink into themselves and say little. Stereotyped words or syllables and movements take the place of embarrassed remarks and gestures. In the aphasia there is a rather characteristic stringing together of syllables like each other in sound, but meaningless. Muscular rigidity may lead to contractures. The progress of this disease to severe dementia is faster than in typical senile deterioration and the onset is rather earlier.

**Prognosis.**—This depends on the previous rate of development of the condition, the general physical health of the patient and any special pathological basis, *e.g.* Pick's atrophy, that may be recognised. Delirious and confusional phases may give a deceptively bad impression, for sometimes, after they clear up, the patient can resume his old routine tolerably well.

**Treatment.**—Since the breakdown of old people is often brought about by their inability to cope with the demands and stresses of a society that is organised for younger people, social measures can do much to delay the time when senile mental changes will make special care necessary. The more satisfying their mode of life, the less will maladjustment and gross failure be the effect of their senility. Although, when senile dementia is clearly evident, treatment will partly consist in providing as easy, familiar and considerate an environment as possible, it would be harmful to leave senile patients idle because they seem listless, or to let them be lonely because they are fretful. Whether institutional treatment is necessary depends not only on the mental impairment but also on the patient's social level and the willingness of his relatives to look after him well enough. Patients often fit surprisingly well into hospital life and routine when this makes due allowance for their infirmities, and provision for their social and psychological as well as their physical needs. Drugs are best avoided, and caution is necessary in letting the patient have the aperients he demands to relieve his—mainly delusional—constipation.

## 2. CEREBRAL ARTERIAL DISEASE AND HYPERTENSION

The characteristic features here are the focal symptoms. All else is indistinguishable clinically from senile and other cerebral conditions; of course, pathologically many senile brains show arterial degeneration too. The early or mild symptoms of cerebral arteriosclerosis are the same as those of "essential" hypertension; and very like those of many benign melancholias of late middle age.

**Pathology.**—Atheroma of the cerebral arteries is accompanied by nutritional changes—softening—in the brain tissue, falling into three stages, *viz.* necrosis, degeneration (with masses of granular phagocytes, containing fats and hæmosiderin)

and sclerosis (in which cavities and scars of glial, astrocyte and mesodermal tissue take the place of the necrotic cells) (see also p. 1443). The cortex on the convexity of the brain may show microscopic areas of perivascular gliosis, but no softening. It is not yet possible to correlate the mental and the cerebral changes in these psychoses, except for the focal lesions.

**Symptoms.**—Since "essential" hypertension often precedes definite vascular disease and itself produces mental symptoms, a description of these symptoms serves also to describe the earlier stage of cerebral arterial degeneration. Along with headache, giddiness, tinnitus, faintness and insomnia, there may be disturbance of speech and writing—the former becoming slow and at times indistinct—and transient pareses and apraxia. Certain traits of personality may be intensified: the patient becomes irritable, egotistic, moody and easily tired, his conversation lumbers along where once it moved easily: he is depressed or paranoid; but there may be wide variation in the intensity of these changes, which are by no means always found. Brief phases of disturbed consciousness, lasting up to 3 weeks, may suddenly occur either in a form very like the "absences" of the epileptic, or as twilight states with hallucinations, ecstasy, incoherence, disturbed motility and agitation.

After this stage of neurasthenia and episodic disturbances, the patient with cerebral vascular disease may begin to have trouble in finding words: he perseverates a little, and is at a loss when anything unusual is required of him. His depression and hypochondriacal worries increase, he is distressed by his own slowness and failures, and may attempt to kill himself. Emotional control falls off so that he weeps and storms when he would rather be calm. Nihilistic ideas may abound—his bowels have not been opened for 6 months, his trunk is a hollow cavity. Nocturnal delirium is frequent. Aphasia and apraxia are commonest after a focal complication.

The most important feature is the way the patient continues to look normal and sensible when already mildly demented. Sometimes transfer to the strange surroundings of hospital is too much for the hitherto well-preserved outward normality, and the patient goes to pieces, as he also may if he has to give up his usual work or move house.

**Diagnosis.**—Because a patient has generalised arterial disease, it does not follow that any psychiatric symptoms he may show are due to the cerebral vessels being thus affected. Unless there are definite focal symptoms, or evidence of dementia, it is unsafe to hold the cerebral arteries responsible and to give a prognosis based on this. There is no known means of distinguishing many benign "neurasthenic depressions" and involutional hypochondrias from those due to disease of the cerebral vessels. If there has not been any history of such tendencies until an attack at the age of 60 odd, the probability that it is an organic vascular disease is much higher. The distinction is all the more difficult because so many unstable persons develop arterial disease in later life; especially those prone to anxiety and other affective disorders. Neurological findings (see p. 1443) may be decisive in a doubtful case. The condition of the retinal arteries is not a reliable guide.

**Course and Prognosis.**—In definite cases of cerebral arterial disease with mental disorder the prognosis is necessarily bad, though the mental symptoms may only progress slowly, and the patient live another 10 or 20 years. Much will depend on such sudden accidents as thrombosis or hæmorrhage. An episodic confusional state, perhaps even one produced by drugs, may suggest a needlessly gloomy prognosis. In cases of "essential" hypertension, the course of the mental illness is dependent on the general disturbance, and is often quite favourable. Symptoms that are apparently hysterical, occurring for the first time in middle life, are of bad omen.

**Treatment.**—Besides the general medical care of such patients, not a little can be achieved by psychiatric methods. In the early stages, where there is much anxiety and depression, too energetic physical investigation and treatment may do harm: reassurance and sedation can do much good. The less said to the patients about

their blood-pressure and their arteries the better. They should keep at work and in their accustomed surroundings as long as they can, unless an acute phase of the illness or depression intervene. Emotional upsets oftener aggravate their condition than physical ones, so they should be cushioned against such jolts. Their depression may necessitate hospital care, especially because of the risk of suicide, or because they are too irritable and neglectful to be at home any longer. If there be dementia, even of mild degree, the patient will probably remain in a mental hospital once he has gone there. It is, however, not easy to be sure about mild dementia being present; it can be counterfeited by passing disturbances, *e.g.* emotional ones.

### 3. HUNTINGTON'S CHOREA (see p. 1519)

## SYPHILIS OF THE CENTRAL NERVOUS SYSTEM

Only the mental symptoms will be described here. Hypochondriacal and depressive reactions sometimes follow infection, or the risk of infection: such psychogenic illnesses do not belong under this rubric; occasionally, however, a patient's anxiety lest he be developing neuro-syphilis turns out to be justified. A syphilitic neurasthenia can occur in the early stages of the disease, due to a mild meningitis. The more severe meningo-encephalitis—*cerebral lues*—may be accompanied by disturbance of consciousness, even to the point of delirium or mild dementia: loss of initiative, euphoria or moroseness, poor judgement and impaired memory may persist and the patient be aware of them in greater measure than he is in general paralysis. These conditions are often complicated by the signs of premature arterial degeneration in the brain. The psychoses that accompany tabs are due to syphilitic changes in the brain, often complicated by alcohol, trauma, heart and kidney disease, and other exogenous factors; there are also depressive hypochondriacal reactions to the pains and other disabilities which the patient suffers.

**GENERAL PARALYSIS OF THE INSANE.**—Dementia is the constant sign of this mental picture; the old descriptions of a "classical" course with an expansive onset are fallacious, but general dementia is almost certain to occur in every case that is not treated. All the other symptoms are either neurological and focal, or due to the patient's constitutional predisposition and previous experiences.

The dementia may at first be quite undetectable as such, because it appears under the deceptive guise of a neurasthenia, melancholia or mania; only gradually does the intellectual impairment become manifest. In the beginning of general paralysis, which is seldom abrupt (though it may need a careful enquiry to verify the prodromal symptoms), "functional" syndromes can be so "typical" and organic changes so slight that the most expert psychiatrist is misled; only by physical and serological examinations can he avoid a blunder. A faint degradation of personality, a lapse in social refinements may be the first indication of what is wrong. Then memory for the events of yesterday and last week becomes less trustworthy, what seemed at first a trivial absence of mind becomes serious incapacity, and yet the patient remains serene and outwardly indifferent to his lapses. As in senile and arteriosclerotic dementia, he may be all right so long as he is in an accustomed rut, but a holiday or a change reveals his infirmity. His mood and interests as the illness goes on become dull or labile, his rages are fleeting, his activities fussy; if, however, he is in a manic excitement, with little dementia as yet, the affective changes can be violent, and indeed dangerous, just as in a depressive phase the patient may kill himself. Sleepy and slow, careless about social usages, inattentive and ignorant of what he once knew well, the more demented patient cannot escape recognition as having an organic cerebral affection. Elementary problems in arithmetic and questions of general information are more than he can cope with. He gives easy assurances that he can do them, or

puts his questioner off with airy explanations (*e.g.* that he has not had his spectacles by him lately); when pressed, he makes bad mistakes or becomes angry. The extent of his failure will, of course, depend not only on his dementia, but on his previous intelligence and habits (*e.g.* a bank manager retains the capacity to do mental arithmetic when much else has gone). Inability to receive new impressions and to relate them to earlier memories co-operates with impaired judgement to give a gross but patchy and fluctuating *amnesia*. Because of these disturbances, and especially the bad judgement, patients may commit offences, ruin themselves by grotesque extravagance and brush aside facts that stare them in the face. They will put up with restrictions on their freedom, forgetting their protests soon after making them; silly reasons are sufficient for their compliance, and a tactfully offered cigarette or joke may divert their thought and feeling from some serious matter that angers them. Their delusions are due to the same disorders of memory and judgement, coloured by their general personality; sometimes they are confabulations, rationalisations for their having forgotten or spoilt something. If the patient had in health tendencies to euphoria and expansive behaviour, grandiose delusions and boasting will be to the fore. It is, however, not uncommon to find a fatuous euphoria, though there had not previously been affective swings and hypomania; in such patients one finds abundant proof of gross impairment of judgement, especially shown as defective insight. The most advanced dementia appears as a helpless, vegetative, bedridden state, sometimes accompanied by gross focal symptoms, such as aphasia and agnosia. The physical symptoms (see p. 1455) are much intermingled with the mental ones, as in the patient's clumsy movements and disturbed speech and handwriting: thus, in his writing he leaves out letters, syllables and words, repeats and transposes them, messes the paper with blots and sputters, writes across the lines, puts in meaningless strokes and leaves his mistakes uncorrected; the tremulous script shows interruptions in the usual smooth alternation and tempo of movement, the letters are of very uneven size and ill spaced. Articulatory and aphasic disturbances may affect the sense, intonation, timbre, rhythm and precision of utterance; they must not be evaluated in diagnosis, any more than the writing disorder may, without regard to the patient's previous normal script and speech and the circumstances under which he was writing or talking, since people, habitually untidy in their enunciation or handwriting, can exhibit many of these symptoms when tired or in a hurry.

Besides the above, atypical mental pictures may be seen either ordinarily or as the outcome of treatment with artificial fever. Paranoid states, hallucinosis, a Korsakoff syndrome, epileptiform excitement, hysterical disorders and catatonic symptoms of every kind (except *flexibilitas cerea*) may occur. Hallucinations are uncommon, except during fever or after malarial treatment; in the latter case they are often of paranoid colouring. Not the expansive form, but a simple progressive dementia is by far the commonest clinical picture; depressive, confusional and hyperkinetic states are almost as frequent as the expansive.

In the "Lissauer" form the slowness of the dementia is remarkable in comparison with the conspicuous focal symptoms, such as the seizures without convulsions or loss of consciousness.

The effects of treatment upon the mental state are of great social moment. In many patients who do well the personality has the edge taken off it, there may be less initiative and force in mental activity, and emotion may be less controlled, especially in the proneness to anger or to frivolous levity, yet the patient is able to return to his former work, even though it is responsible and complex; he could scarcely, however, except in the most favourable cases, learn a new job or adapt to new and exacting situations.

In the "juvenile" form there may be premonitory symptoms of excitability, grizzling, timidity and backwardness at school. Gradually the symptoms of dementia become plain, and if the onset be early enough, symptoms usually found in severe

## OTHER CEREBRAL DISEASES

**LETHARGIC ENCEPHALITIS.**—The mental disturbance of the acute attack may merge into a hyperkinetic excitement, with choreiform and athetoid movements, insomnia, generalised pains, mild delirium and, occasionally, catatonic symptoms: this seldom lasts more than a few weeks. There may be subsequently a neurasthenic fatigue and irritability with headaches and poor sleep. The distinction between what is neurological and what is psychiatric in the symptoms could scarcely ever be more difficult than in this disease. The motor disturbances, such as oculogyric crises, are not merely responsive to emotional and other psychogenic influences, they are inseparable from concomitant mental happenings (e.g. the surging up of anxiety or obsessions), and whole patterns of complicated behaviour, e.g. breathing, may be involved. The motor rigidity of the patient's Parkinsonian state may be paralleled by a lack of the normal drive and fluidity of thought or behaviour. Memory, however, and grasp are unaffected. The obsessional symptoms sometimes occur quite apart from oculogyric crises, and may greatly distress the patient. Depressive phases may result in suicide, which is fostered, as it were, by the keen appreciation which many patients have of their ruined careers and their almost imbecile appearance, so different from what they were and, indeed, from what they still know themselves to be. Paranoid, and especially schizophrenic, symptoms may develop in the later stages.

The younger the patient the more likely is it that he will develop disagreeable anomalies of personality, and have attacks of restlessness or even be permanently restless. Many children and adolescents after their acute attack become social problems: they play stupid or cruel tricks, they set every one they can by the ears, they may steal, behave sexually in an outrageous way or accuse others of sexual offences against them. Their activity is not always purposive, nor always antisocial; they make the same impression as a monkey might who is sometimes mischievous but always on the move. There may be no Parkinsonism in these cases. The prognosis is not good, and they almost always do better when subjected to the régime of an appropriate institution; they do badly at home or in places where what may be termed normal delinquents and "social problems" are cared for.

**SYDENHAM'S CHOREA.**—The usual mental changes here are lability of affect and irritability. These are seen as naughtiness, outbursts of anger or crying, resentment at sudden noise or light; in others there is lessened spontaneity, often masked by the choreic movements. In more severe cases, especially in older children, these changes are accentuated; in the fleeting phases of anger or terror there may be slight delusional trends. Still more severe forms, with delirium, hallucinations, delusions of persecution and much excitement, are seen in adults, e.g. in chorea gravidarum.

The tics and compulsive utterances (Gilles de la Tourette's syndrome) which may follow chorea are evidence of the interplay between hereditary, psychic and structural factors. Chorea is more prone to occur in those whose families show nervous disorders, especially schizophrenia. The motor after-effects, especially tics, appear and disappear under emotional influences; they are also conditioned by the original choreic disturbance of neuromuscular function. The obscene ejaculations of la Tourette's syndrome are dependent on much the same articulatory and respiratory hyperkinesias as are the breathing spasms of encephalitis lethargica, though

they are also dependent on psychological tendencies and experiences. They illustrate how psychological influences work through available bodily structures and functions, whether morbid or healthy. The obsessional element in this affection is comparable to that in encephalitis lethargica.

**DISSEMINATED SCLEROSIS.**—Slight deviations from mental health are frequent, but obvious ones rare in this disease. Affective lability may be conjoined with a slight disorder of judgement, so that a baseless euphoria develops, but this is not universal, and many of the patients are depressed. Acute outbursts of excitement, hallucinosis or delirium occur in a few cases, and dementia in the advanced stages. The most important mental disorder in them is that which appears as hysteria. A hysterical personality has not been present in these patients before the disease began, and the symptoms are in that respect only dubiously hysterical: they do, however, in other respects conform, in that they can be evoked psychologically and removed psychologically; they may centre on, and elaborate, actual anomalies, *e.g.* of movement or sensation, and may still yield to hypnosis or other psychological measures. They can greatly confuse the diagnosis.

**SCHILDER'S DISEASE.**—In this disease profound dementia gradually develops along with the blindness, deafness, aphasia and agnosia and other focal symptoms. In the juvenile cases there may be at first disturbances of behaviour like those of juvenile encephalitis lethargica.

**PARALYSIS AGITANS.**—This may be accompanied by hypochondriacal depression. Sometimes this is an expression of the cerebral disease which also causes the Parkinsonism, and in that case the prognosis is bad; sometimes it is a recurrence of depressive attacks which have occurred at times of stress earlier in the patient's life, and then the outlook is fairly favourable. Senile dementia is, of course, not infrequent in these elderly patients.

**CEREBRAL TUMOUR.**—Apart from any aphasia and apraxia, the mental state here is more closely related to general intracranial tension than to any local disturbance. The size and rate of growth of the tumour are therefore important in this regard. If rapidly growing, there is more disturbance of consciousness, with impaired memory, disorientation, incoherence and, sometimes, hallucinations and confabulation; this clouding of the mind fluctuates a good deal. In more slowly growing tumours, lucidity is preserved and change of disposition is the prominent feature. The patient's earlier tendencies get freer play, unsuspected ones appear, and a series of foolish investments, for example, or homosexual escapades may for years divert attention from the organic disease. The moria, or fatuous wit and cheerfulness, often attributed to frontal tumours but also found in other cerebral diseases, may give the impression of being a hysterical pseudo-dementia; other apparently psychogenic symptoms may prove misleading. A straightforward depressive attack can occur, or indeed any "functional" syndrome.

Hallucinations may depend on a focal lesion, as in the cases in which they are limited to the hemianopic field, or are solely of taste and smell.

**CEREBRAL ABSCESS.**—The mental symptoms are those of tumour with or without others due to meningitis.

**ACUTE MENINGITIS.**—There may be delirium, preceded during the prodromal stage by irritable apathy, and followed by months of moody neurasthenia.

**CEREBRAL TRAUMA.**—After concussion, there is commonly retrograde amnesia, and there may be, later, also amnesia for events following the injury; the extent of this depends on the severity of the damage. Delirium may ensue; it has little that is characteristic, and is more frequent in alcoholic and elderly people. A Korsakoff syndrome may develop. Twilight-states are rather more common; during them acts of violence may be committed, as in epilepsy, and afterwards quite forgotten. Traumatic epilepsy may follow. The later changes in personality are commonly those that may be found lingering after any toxic or other structural impairment of

the brain. But sometimes the disturbance of consciousness is more persistent, the intellectual damage greater, *the deterioration progressive*; in such cases there is usually cerebral arterial disease, an unrecognised alcoholism, cerebral tumour, general paralysis of the insane, or some other complicating factor. In predisposed persons the cranial injury may be responsible for a melancholic attack, schizophrenia or other "functional" syndrome; the prognosis is usually good even if the illness lasts many months.

Minor symptoms which may be hysterical occur frequently after cerebral trauma. This is partly because of the site of the injury, which favours vague physiogenic symptoms that respond readily to emotional and other psychological influences. Many of these symptoms are, however, produced by psychical rather than physical mechanisms. Not injured cells, but mental attitudes are at the bottom of the tremblings, faintings, weakness, paræsthesiæ and other troubles so often the sequel of a trauma in itself little likely to have such effects. They are not responses to the actual injury, but to the situation created by the injury. It is as unwise to dub all such vague post-traumatic phenomena hysterical as to attribute them entirely to the direct injury. If there is slight amnesia of the typical kind, with difficulty in concentration and headache, it is fairly probable that these are physiogenic residues; if there has been an interval between the actual concussion and the appearance of the indeterminate symptoms, a history of psychopathic predisposition and an adequate psychogenesis (e.g. economic fears and insecurity, or claims for compensation, with repeated medical examinations, and patent uncertainty among the experts) the condition is likely to be neurotic. Much will, of course, depend on the neurological and other findings, including the demonstration of localised lesions; thus, damage to the frontal lobes may much change the personality, and in other sites be responsible for an apraxia, say, or a visual defect. Too rigid and doctrinaire an insistence on discriminating neurogenic from psychogenic residues of the injury can be harmful; the main matter is to prevent neurotic attitudes and symptoms from developing, or if already there, from continuing.

The degree of intellectual impairment can sometimes be measured, and the departure from normality demonstrated, by psychometric methods (see p. 1684). Among the tests employed those which require a capacity to deal with abstract concepts (e.g. sorting objects according to qualities they have in common) are particularly informative.

**EPILEPSY.**—Although the motor seizure is the chief symptom of epilepsy and the decisive one in diagnosis, there are minor or equivalent symptoms, as well as delirium, twilight-states and dementia, to be included among the mental disorders of this illness.

Instead of a major fit the patient may become unconscious; or he may pass into a twilight-state in which for a few minutes or longer he wanders about in a dazed way and does inappropriate things, having afterwards complete amnesia for all this; or there may be a sudden interruption of action and speech, during which the patient remains immobile or makes some automatic or aimless movements. Epileptic furor is a delirious state in which acts of violence may be committed: it lasts often for several days, is accompanied by disorientation and hallucinosis, and is much rarer than is popularly or forensically supposed. All the states of disturbed consciousness mentioned above are most often seen as equivalents for a seizure; the twilight-states, however, may precede the motor attack, follow it, or be accompanied by a few violent clonic movements.

Apart from their seizures, epileptics are prone to swings of mood—towards anger, shallow sentimentalism or depression—which may pass over into a fugue, during which the patient wanders a long way from home.

The likelihood of dementia later cannot be inferred from the symptoms of the epilepsy, except that it is greater if attacks occur very often. Apparent dementia may be the result of intoxication with anticonvulsant drugs, or of the idleness and sterile

in an institution. When there is genuine dementia, it begins as a faint loss of rest and concentration, with increased sensitiveness to supposed slights, then memory falls off somewhat, the trivial and the important are muddled together, and the patient talks with much circumlocution; he is fond of needless system, assumes parades virtues he has not, *e.g.* an intellectual bias or a devout spirit, and is child-pleased when anyone praises him. Later, a profound dementia may supervene, this is not common; it is unlikely that the changes of character just described are part of a dementing process; many epileptics who exhibit some of the most dis-able features of this sort never become plainly demented, and many severe epileptics are free not only from dementia but also from these traits. There is ground regarding this impulsive, pretentious, fawning and snarling way of some epileptics partly a variable expression of their constitutional predisposition (to which the seizures are likewise due), and partly as a reaction to their situation. Con-sequently it is much less evident, or not evident at all, in those who in spite of their lives live comparatively normal lives.

**MIGRAINE.**—Occasionally sharp changes of mood, behaviour and personality may take the place of the ordinary attack with headache. It has often been observed that emotional stress may precipitate an attack, and psychological guidance which im-proves emotional stability has been found to lessen the frequency and severity of attacks in many patients.

## INTOXICATIONS

### 1. ALCOHOLIC DISORDERS

Alcohol is so permissible and trusted a poison, so easy of access for those who wish to escape from their troubles, that it is resorted to in excess by maladjusted persons; consequently its effects may complicate or be complicated by the psycho-pathetic anomaly which favoured the taking of the drug, *e.g.* episodic excitement or depression, anxiety, cerebral arterial disease, paranoid states, hysteria. The acute effects of a single dose of alcohol are either the well-known phenomena of intoxication, or an excitement (*mania a potu*) sometimes with clouding of consciousness. The excitement is commoner in people with cerebral trauma, arterio-sclerosis, epilepsy and unstable hysterical personality, and in them may lead to acts of violence; rarely may occur in normal persons who have taken alcohol when they were exhausted or upset.

In chronic drunkards, a dementing *demoralisation* can occur. Their narrowing interest, superficiality of thought, weakness of memory and moral decrepitude are reminiscent of what happens in many epileptics and some early general paralytics. The crudeness and even brutality of their conduct is in ill accord with their maudlin prating about virtues and their pot-house jollity. The mood of these men can be as labile as their abandonment to it is constant: they pass from rage to weeping, and enough soon after, with no shame for themselves and no thought for the miseries they put on their families. Such degradation is, of course, far from being the rule: some chronic alcoholics become only cheap editions of themselves, with their former qualities underlined or smudged rather than defaced; they are perhaps weak and irritable, untrustworthy or lying, but not given to savage fury, nor grossly damaged in judgement and social feeling. Some of them develop delusions, especially of jealousy. They collect, as paranoid people of other kinds do, scraps of alleged evidence which they piece together to prove their suspicions right; complicated delusions of persecution, however, they rarely develop. Sometimes the delusions of jealousy fade as the patient gets more and more facile, but more often they persist as a chronic insanity and are of the greatest danger to the suspected wife; murder is not unknown in such cases.

The nature of the delusions is to be attributed in part to the lessened sexual potency of chronic drunkards and to the domestic wretchedness and aversion they often create, as well as to the same causes as in "functional" paranoid states, where such delusions are also common, especially in middle life.

The symptoms of *delirium tremens* would appear to differ in nothing but severity from the essential symptoms of any delirium (see pp. 1625, 1639). Some observers, however, deny this. The anxiety amounts to terror, mixed oddly enough with euphoria; optic and cutaneous hallucinations are vivid and restlessness can be extreme. There is almost complete sleeplessness, and much disorientation as to time and place, but not as to personal identity. The patient's attention wavers between his hallucinated and his actual surroundings, but can usually be caught and held for a few moments. He is very suggestible, as most chronic drunkards are; pressing on his eyeballs, for example, will very likely make him see whatever one tells him he sees, and he will read aloud from a blank sheet if one wants him to. Among the visual hallucinations may be miniature ones (micropsia), and many illusional perceptions. The content of the hallucinations changes rapidly, and a false perception in one field (e.g. a vestibular one) tends to evoke others (e.g. of sight, touch or hearing). Insight is commonly lacking; afterwards there is patchy amnesia for what has happened in the delirium. The death rate, with adequate treatment, has been about 1 in 7; and of those who die most of the men are under 40, and most of the women under 45.

In *acute alcoholic hallucinosis* auditory hallucinations of a persecutory kind are prominent and consciousness is not notably clouded. It is rarer than delirium tremens, and is more prone to follow a bout or orgy of drunkenness. The patient is frightened, but not obviously out of his mind; he is correctly orientated and may be able to go about his business for days. Auditory hallucinations are vivid and insistent, after a premonitory phase in which there are sensitiveness to sounds, and roaring, singing, hissing, etc., in the ears. Tormenting voices, sharply localised but seldom fastened upon bystanders, abuse, threaten or discuss the patient; they may say his wife plays him false, order him to kill himself, describe his every movement, especially at private moments in the bath or lavatory, cast up his more shameful secrets at him, shout his thoughts aloud. There may be many voices of men, women and children, all talking together and perhaps rising and falling in the same rhythm as his pulse. They are so real that the patient answers them; he may be in doubt about the presence of his tormentors and may shout back insults to see if a blow will follow from the owners of these evasive pursuing voices. Hallucinations of sight and other senses are far less prominent than those of hearing; cutaneous ones, e.g. of being sprayed with a cold liquid, are not uncommon. Delusions are usually inconspicuous: they are, as a rule, attempts to account for the hallucinations, and they commonly fade out of the picture or pass into a chronic persecutory disorder. Flight or acts of violence may result from the patient's fear or anger. Usually it is a matter of only 2 or 3 weeks before the hallucinosis clears up, if no further alcohol be drunk; sometimes, however, a delusional state, more rarely a Korsakoff picture, supervenes in predisposed persons. *After recovery, there is little or no amnesia for the events of the hallucinosis. Relapse is to be feared if the drinking goes on.*

The *Korsakoff* syndrome is not invariably associated with polyneuritis. Nor, as stated on p. 1627, is it limited to alcoholism; it can follow other severe chemical and mechanical injuries to the brain. In alcoholics it is commoner in middle life, developing either insidiously in the course of chronic alcoholic demoralisation, or after delirium tremens; women are especially prone to develop this syndrome after the delirium. The symptoms have already been described. The disorientation, superficial appearance of clarity, incapacity for initial perception and subsequent recall (extending often to most of the material of memory) yet with retention of some capacity for learning by repetition, along with confabulation, dullness of emotion

and initiative, and grossly impaired judgement making a striking picture. Complete recovery is on the whole uncommon, occurring in less than a quarter of all cases. The mortality rate is higher in women and older people, in those with acute onset and with a red-cell count below 3,000,000, or with a rise in the protein content of the C.S.F. It does not correlate with the severity of the peripheral neuritis.

*Chronic delusional states* have been referred to above; they are sometimes called alcoholic paranoia, but inappropriately so; jealousy is the commonest and most dangerous feature. Alcoholic epilepsy has been described. It is a symptomatic epilepsy, often atypical; sometimes in unstable hysterical patients it may be brought about through overbreathing when intoxicated.

**Diagnosis.**—The diagnosis of alcoholic psychoses must depend much more on a history of drunkenness in any patient than on his clinical psychiatric features, none of which are limited to alcoholic disorder. Since, however, alcohol is far the commonest cause of most of the toxic abnormalities described, it can be safely presumed in some cases in which the certain history of addiction is unobtainable.

**Differential diagnosis**, so far as aetiology is concerned, will turn on somatic findings, including the results of chemical tests. If the form of the disorder is in question, the chief diagnostic difficulty arises with acute hallucinosis and the chronic delusional varieties. A hallucinosis of similar type can occur in schizophrenia and in affective disorders, but in the latter is recognisable by the ideas of self-reproach expressed; the differentiation from schizophrenia is difficult, since in many of the cases the progress of the disorder is towards a chronic schizophrenic psychosis, and one may suppose that in these patients the intoxication had activated, as it were, the same mechanisms as those involved in schizophrenia, or had complicated a schizophrenic illness. This applies also to the chronic psychosis with delusions of jealousy. There is no value in differentiating carefully the clinical varieties of alcoholic psychoses, since they overlap.

**Treatment.**—Social prophylaxis is the main thing. The incidence of alcoholic psychoses in England is less than a third of what it was 40 years ago, and this may be attributed almost entirely to social influences. Individual prophylaxis is scarcely to be considered, save as a by-product of psychiatric treatment, since a great proportion of unstable persons are potential drunkards, and in any case we cannot yet tell which alcoholics will become mentally ill through their drinking. Social prophylaxis is so immeasurably better in forestalling alcoholism and the psychoses and degradation that sometimes spring from alcoholism, that deliberate individual prevention is here negligible.

When alcoholism is itself to be treated, independently of its ill-effects upon mental health, the problem is that of any drug addiction. Absolute removal of the drug is essential in the first place. This may be effected for a time by getting the patient into a hospital or home where he cannot obtain the alcohol he desires, but to ensure that the patient who has had years of excess shall henceforward be able to put aside alcohol while it is within his reach a great emotional upheaval, e.g. bereavement, religious conversion, fear of death, and considerable changes in his human environment are required. These are provided, for instance, by a semi-religious organisation of former drunkards, called Alcoholics Anonymous, which had its rise in America and which has had notable success in the last decade. For the most part, treatment of alcoholism without restrictions upon access to the drug is a failure; the restrictions must at first be imposed from without, not left to the patient's self-control and judgement. Psychotherapy is a necessary feature of the treatment in the many cases in which inner struggles and neurotic disabilities have been the basis for the addiction; it must, however, be conjoined with vigorous social measures (see pp. 1618, 1619).

Methods which aim at "conditioning" the patient to have a distaste for alcohol are sometimes successful. The unconditioned reflex of nausea and vomiting (evoked by emetine) is linked up with the sight, smell and taste of alcohol. Thoroughly

for general paralysis because of the ataxia, tremor, articulatory disorder and other neurological signs. Recovery is the rule when the drug is stopped. Picrotoxin may be needed for acute poisoning. For the addiction itself, essentially the same problems and methods of treatment are in question as with other drug addiction. This applies also to *ether*, *chloral* and *paraldehyde*.

*Mercury* and *lead* poisoning may lead to mental disorder (see pp. 368 and 382); *manganese* to a Parkinsonian syndrome with compulsive symptoms (reminiscent of *encephalitis lethargica*) and a mild paranoid or euphoric dementia; and *benzene* or *carbon disulphide* may cause delirium.

*Acute carbon monoxide poisoning* in rare instances leaves behind severe mental disorder of the amnesic-aphasic kind, which may not become apparent until several weeks after the recovery of consciousness. More commonly, it results in a clinical picture almost indistinguishable from hysteria; this may take months to clear up, and is in no wise benefited by psychotherapy. Chronic poisoning by small quantities of carbon monoxide causes neurasthenia.

## INFECTIONS AND EXHAUSTIVE DISORDERS

### 1. INFECTIOUS TOXÆMIAS

Delirium and a Korsakoff syndrome are the more acute, and neurasthenia the milder, signs of mental disorder due to an infectious fever. In many of the cases, however, in which mental disorder is attributed to "sepsis" or other infection, either the mental changes are unconnected with the infectious process or there has not been an infectious process, as is often found when one enquires into an alleged attack of "influenza" and finds it was nothing of the kind. There are three possibilities: the mental changes are mainly due to the infection; they are independent of the infection; they are partly due to the infection and partly to other, usually constitutional, causes. The depression that occurs in and after many infections is usually of the third category mentioned; delirium instances the first possibility; and the second is often exemplified when some non-organic syndrome is put down to sepsis, *e.g.* in the tooth-sockets.

Wherever a delirium or other mental disturbance of one infection differs from that of another, *e.g.* the delirium of typhoid from that of pneumonia, the difference lies only in the severity and duration of the physical effects of the intoxication and in the peculiarities of the affected person; no mental symptoms specific to any one infection can be demonstrated. Among the individual peculiarities just mentioned must be included a constitutional predisposition or readiness to respond with symptomatic psychoses to mainly physical ills.

There are a few infections that hardly ever cause mental disturbance, *e.g.* tetanus and diphtheria; others do so by their local cerebral incidence, *e.g.* malaria or *encephalitis lethargica*. *Tuberculosis*, from its chronicity and its occasional incidence on the central nervous system, has a special position. Its treatment, moreover, especially in the pulmonary form, necessitates an abnormal, unsatisfying life for a time, and this with the toxæmia seems to be responsible for euphoric or anxious restlessness in which erotic tendencies and irritability are often prominent. *Spes phthisica* is partly attributable to toxic euphoria, in part it is a form of over-compensation for fear.

### 2. EXHAUSTION AND INANITION

These, especially if conjoined with some shattering experience—an earthquake, incessant bombardment, a bereavement—bring about severe mental disturbance, *e.g.* a twilight-state or a delirium. *Hæmorrhage* and *cachexia* may be responsible for "light-headedness", as in advanced carcinoma, or after a severe operation.

## METABOLIC, ENDOCRINE AND VISCERAL DISEASE

## 1. METABOLIC DISORDERS

Various metabolic disorders can similarly, *i.e.* non-specifically, affect mental health. *Diabetes*, for example, which is especially frequent in families with a predisposition to affective psychosis, may be accompanied by transient phases of depression, anxiety or excitement which correspond to changes in the blood-sugar level, or a ketosis may be ushered in by mild delirium. A diabetic pseudoparesis, with peripheral neuritis, may cause slight difficulty in diagnosis. In children, mild hypoglycæmia may be responsible for anxiety, naughtiness and other disturbances of behaviour. Anomalous psychic states may be produced in the rare condition of hyperinsulinism, and be mistaken for hysteria or an anxiety state of the psychogenic sort. *Gout* may occur in people predisposed to affective disorder; often a depressive phase precedes an attack. Alkalosis and anoxæmia may each be the cause of mental disturbance of the organic type. In *pernicious anæmia* there may be symptoms, *e.g.* an acute confusional state, referable to the structural changes in the central nervous system, but more often depression occurs without "organic" features; mania can also occur, and in some cases a chronic paranoid condition. The more "organic" the picture, the poorer the prognosis for a return to mental health. Of deficiency diseases *pellagra* is the one most commonly productive of mental disorder. It must be remembered that a long-standing anorexia, of psychogenic origin, or occurring in the course of a chronic melancholia, may itself lead to a pellagroid condition, so that the symptoms of mental disorder will then be those of the original illness plus those due to the deficiency. The clinical picture is sometimes very like that of hysteria; or the usual organic syndromes may be produced, especially florid confusion with perhaps hallucinations of fire. The nutritional factor in alcoholic psychoses, especially Wernicke's encephalopathy, is prominent.

In the metabolic disorders just mentioned the physical phenomena are relatively coarse and obvious. It is in some cases proven and in others highly probable that less obvious metabolic disturbances are among the primary symptoms of "functional" mental illness, or are its pathological basis. The acid-base equilibrium and the electrolytes of the blood, the metabolism of carbohydrate, fat and protein, and the chemical regulation of the vegetative activities are all, in such forms of mental illness as schizophrenia and mania, subject to changes which have not as yet been used in the pathology or treatment of these conditions, because the findings are not sufficiently constant or specific.

## 2. ENDOCRINE DISORDERS

These play a more prominent rôle in the investigations than in the clinical practice of psychiatry. Many endocrine preparations have, it is true, been administered to schizophrenic, sexually perverted and melancholic patients, either empirically or in accordance with a premature and ill-devised theory, but the good results of all this are negligible. Oestrogen treatment of menopausal neuro-vegetative symptoms is a rational procedure, but the blind use of endocrine substances in psychiatry has had its day.

*Exophthalmic goitre* is more prone to occur in anxious, nervous people, especially after some sudden shock. The usual concomitants—restlessness, tension, irritability, difficulty of concentration and liability to sudden changes of mood—may be complicated by a definite mania or depression and, if the disease be severe or advanced, delirium and confusion may supervene. Though such organic syndromes mean, as a rule, a bad prognosis, they sometimes clear up dramatically after operation. The interaction of constitutional and psychogenic factors with the actual thyrogenic

intoxication makes some treatment of the anxiety by psychological as well as other methods desirable in many cases of exophthalmic goitre, either as a preliminary or supplement to partial thyroidectomy.

In adult *myxædema* the slowing of mental activity may sometimes be accompanied by a chronic paranoid psychosis, or there may be a phase of excitement with hallucinations; the variety of syndromes that can occur is referable to pre-existing constitutional tendencies and to the varying severity and rapidity of development of the thyroid deficiency. An apparently "functional" syndrome may precede the overt *myxædema*.

Juvenile and congenital *myxædema* are described elsewhere (see p. 496).

*Tetany* may be signalled by epileptiform seizures, or there may be a proneness to psychogenic fits; thus the patient may spontaneously overbreathe until a convulsion is induced. Hysterics sometimes use hyperventilation in this way. In severe tetany a resistive lethargy or an excited incoherent confusion may occur.

*Pituitary* diseases are more often accompanied by mental symptoms that are a comprehensible reaction to the physical symptoms than by organic syndromes; the latter when they occur may be due to increased intracranial tension. In acromegaly, depression, reserve, touchiness and irritability are not surprising, though some acromegalics remain cheerful as long as their disabilities are moderate, and sometimes there is a blindness to the disease, a lack of insight, even when it is advanced. In dystrophia adiposo-genitalis a rather childish placidity may be met. In adiposa dolorosa depression may be severe, or hysterical symptoms may develop. Simmonds's disease may be accompanied by depression, severe anorexia, reaction to the psycho-sexual disturbance, and, in the later phases, by organic syndromes due to the cachexia. Similarly, disorders of pituitary function have been found in some cases of "anorexia nervosa". In Cushing's basophil syndrome depression and other mental disturbances can occur.

*Addison's disease* is accompanied by a neurasthenia of which for a time the physical basis may be quite overlooked (as may also occur in myasthenia gravis); in the later stages delirium has been known to occur.

Acute anxiety attacks may occur from a pheochromocytoma. Some persons during the course of treatment with cortisone or corticotrophin develop an acute psychosis which clears up if the drug is withdrawn.

*Sexual epochs* may in women be associated with mental disorder of the organic type, e.g. some psychoses of pregnancy and the puerperium. During pregnancy plain psychosis is rare, but hysterical symptoms, depression and anxiety are fairly common, especially if the mother is reluctant to have another baby; a gross psychosis may, however, break out during the latter months of pregnancy. The organic mental syndromes may develop along with polyneuritis, eclampsia or chorea gravidarum. Termination of the pregnancy is called for on account of the mental condition when there are symptoms of organic psychosis which are likely to get worse, a history of suicidal attempts or infanticide in connection with previous pregnancies and a depression again in this one, or if on other grounds there is a clear risk of suicide or other untoward result of the mental illness, should pregnancy continue. The decision is often a very difficult one, requiring an expert knowledge of psychiatry for the careful appraisal of aetiology and prognosis essential in every case. The question must turn mainly on the therapeutic value of terminating the pregnancy, so far as the mother's mental state is concerned, as well as upon the stage of pregnancy reached.

In the puerperium "functional" psychoses often develop in predisposed women; if there be septicæmia as well, a confusional state or a delirium, followed by a period of neurasthenia, may occur. In many cases the delirious puerperal psychosis clears up in a week or two; the more endogenous varieties have sometimes a less satisfactory outcome than their form and onset suggest. Infanticide may occur in a puerperal psychosis, especially if the mother has, while pregnant, felt resentful at

having a baby or been troubled by murderous preoccupations, *e.g.* obsessions. Psychoses of lactation are rare, and seldom of the organic type. Menstruation is apt to be associated with depression, irritability and languor in many women, especially during the few days before the period begins; there are no menstrual psychoses but the liability to suicide and to psychopathic reactions is somewhat higher at this time. There is no satisfactory evidence that the affective disorders of later middle life ("involitional melancholia") are caused by the endocrine changes of the menopause; they are certainly not benefited by oestrogen therapy. Puberty and the climacteric are periods of stress during which schizophrenic and affective disorders may occur. The effects of castration are dependent on the age at which the gonads are removed: intellectual development is unaffected, but the emotional and conative activities of those castrated in adult life may be impaired. Neurasthenic symptoms are frequent, and in women anxiety symptoms may appear.

### 3. VISCERAL DISEASE

This may be directly responsible for mental disorder of the organic type. Thus cardiac disorders predispose to an anxiety, which at night may take the form of mild delirium, with restlessness, terror, disorientation and auditory and sometimes visual hallucinations. With improvement in the circulation, the mental symptoms disappear, or remain only as a moody unrest. Reference has already been made to arterial hypertension (see p. 1630). The connection between alimentary disorders and neurasthenic states is well attested, and is striking in children. Jaundice may be accompanied by severe depression, but seldom leads to delirium, save in the case of acute yellow atrophy. *Uræmia* may disturb consciousness greatly, in the form of any of the organic syndromes, from a twilight-state to a euphoric dementia; a Korsakoff condition can occur, but is infrequent.

The psychological causes or accompaniments of many visceral diseases have been diligently studied, and the conditions in which they appear prominent are sometimes called psycho-somatic. The problems raised are intricate, and the interplay between the physiological and the psychological aspects of the disease processes has not as yet been fully disclosed in any of the major conditions studied, *e.g.* ulcerative colitis, peptic ulcer, bronchial asthma.

### AFFECTIVE DISORDER

This is of three types :

1. Manic excitement and hypomania.
2. Melancholia and mild or neurasthenic depression.
3. Agitated depression and anxiety state.

There is in each case a major and a minor form. Each is related to a more or less characteristic personality, and for each the cause of occurrence may be chiefly environmental or chiefly hereditary. Combinations are frequent (mixed forms), or there may be successive appearance of the different types, often with an interval between the attacks. A benign outcome or periodic course is the rule for the major forms, but not for the minor, which often tend to become chronic. This is partly because the environment can have more influence, whether for good or bad, on the course of the minor than of the major, more explosive and sweeping, forms. It would be a very convenient thing if endogenous cases could be sharply differentiated from psychogenic ones, as in the Kraepelinian scheme, but it cannot be done.

*Ætiology.*—INTRINSIC.—Heredity is the most constant single cause. Research has been mainly into the major manic-depressive cases. The genetic factor is weakly

dominant. It may be that more than one gene is concerned, but this is hard to tell, because the predisposition to an affective disorder may be latent in persons who have not been subjected to the stresses that would make it manifest, and consequently the usual Mendelian figures are not to be expected. The present state of knowledge is illustrated by studies on manic-depressive twins, among whom 69 per cent. of those monozygotic (i.e. with identical heredity) were alike affected with the disorder, while the corresponding figure was only 16 per cent. for the dizygotic pairs (i.e. with dissimilar heredity). In the 31 per cent. of monozygotic twin pairs who were not alike in respect of mental illness, the difference must have lain in the environment, thus showing the relative importance of external factors in causing the inherited tendency to become manifest. Although not manifest as illness, the inherited tendency may express itself in bodily and mental constitution.

The bodily habit that is found in a majority (not the overwhelming majority) of those with affective psychoses is called *pyknic* or *eurymorph*. It is best seen in men after the age of 30. It is characterised by large visceral cavities (head, thorax, belly), a tendency to fat on the trunk, slender shoulder girdle and extremities, stocky build, a broad face on a short massive neck, thick receding hair and, later, baldness, venules on the cheeks, and a disposition to arthritis, gout, diabetes and especially arteriosclerosis. As this John Bull build is so common in mentally healthy people, it cannot be regarded as a precursor of mental illness, but only as an indication that some of the constitutional and genetic causes, or biological requirements, for affective psychoses are present.

The same is true of the mental constitution or personality. Here there are several groups, shading off on the one side, by way of cyclothymia and other intermediate forms of mild disorder, into definite affective psychosis, and on the other into normal and stable personality. There are those with a pervading gloominess, pessimism and feeling of insufficiency that spoils their lives; others who are for ever anxious, keyed-up, wondering whether something has gone wrong or will go wrong, and whether it is their fault—careworn worrying creatures; while a third group is made up of the lively, enterprising, confident, sociable people, whose euphoria is patent. Irritability may be found in any of these groups, especially the second and the last. Contrasted or different features are often found mixed in the same patient. The most striking characteristic of the personality of manic-depressive patients is their ready responsiveness and lability of mood; they fluctuate with their surroundings, and in many instances pass suddenly and with small occasion from one mood into another far removed from it.

The signs of affective illness may appear in childhood, though major outbreaks of mania, depression or agitation are rare before puberty. When these occur, the phases are usually brief and the environmental influences strong. Milder forms are often regarded as normal, since night-terrors and other fears, mischievous gaiety and sulky gloom are all familiar enough in children; it is the degree, occasion and persistence of the affect which must decide whether it is morbid.

The psychological crises of puberty are only occasionally affective—chiefly self-reproachful depression or agitation—but during adolescence the illness becomes more frequent; it seldom, however, calls for mental hospital care. Each menstrual period may be accompanied by depression or restlessness, usually coming on about 2 days before the period. In the third decade of life the number of cases steadily rises, and there is another peak in frequency between the ages of 45 and 55. The latter, "involutional", cases show the influence of age strikingly, so much so that they are often considered as separate disorders.

There is little to choose between the curves of age incidence for morbid depression and morbid anxiety of whatever degree; for mania the frequency is highest before the age of 30, as also for affective illnesses with a strong confusional flavour. Pregnancy is frequently accompanied by depression and agitation; psychological factors

are mainly responsible. After childbirth, though there be no septicæmia, affective illness can occur, running a typical and often lengthy course.

The female climacteric is a time when anxiety usually mounts, and is accepted as an ineluctable effect of "the change". It may become definite illness, persisting even for 2 or 3 years. It is doubtful whether there is a specific connection between the endocrine causes of the menopause and so-called climacteric insanity; the melancholia then coming on is like the melancholia of 5 or 10 years later, or the melancholia of middle-aged and elderly men in whom the endocrine changes are not the same. The influence of sex as a whole is obscure. Women have this illness more than men, though the manic form is relatively more frequent in men. The reactivity is often greater and the syndrome less clear-cut in women.

There are geographical differences, sometimes thought to be racial, in the incidence, but the little that is known points to environmental rather than intrinsic causes for this. It has been suggested that affective psychoses are commonly linked with high intellectual gifts; another says they have affinity with mental defect. The former statement has better support than the latter, but both probably are fallacies depending on the material selected for study.

**EXTRINSIC.—Physical.**—Chronic toxæmia and acute infections, especially influenza and pneumonia, can be responsible for the illness. Various drugs help to heighten the anxiety to a morbid degree, e.g. alcohol in certain circumstances, insulin or hyoscine. Cerebral trauma may provoke an attack. The list of physical factors could be much added to, but it must be borne in mind that wherever a distinctive, rather than incidental, physical cause can be found, the condition passes over into the category of organic psychoses. The most difficult cases in practice are those in which there is a question of cerebral arterio-sclerosis or exophthalmic goitre; the affective disorders indisputably due to these two diseases may be quite indistinguishable from others for which there is no such organic basis. The problem here is clinical rather than fundamental; since vascular, cerebral, endocrine and autonomic functions are particularly concerned in the mechanism of emotional change, certain disturbances of the physical apparatus will necessarily be accompanied by many of the psychological phenomena of these emotional changes. The depression of paralysis agitans and the anxiety of coronary disease are of the same order. The notion that coitus interruptus and other sexual practices produce anxiety is unfounded, but they may contribute to it by psychological means.

**Psychical.**—A recent misfortune, commonplace or tragic, may be the cause. Any calamity to which human beings are liable may provoke an affective breakdown. Sometimes it is induced by the insanity of a close relative. However trivial it seems to outsiders, the event that has precipitated an affective attack has been felt as a catastrophe by the patient; there are no records of great and sudden happiness causing an affective psychosis. The nearest approach to a specific connection between the precipitating happening and the type of affective illness is seen in the anxiety disorders which follow a terrifying experience such as exposure to shell fire and bombardment from the air; morbid depression following bereavement, financial setbacks or degradation is an understandable response, it is true, but to ascribe the type of response directly to the nature of the experience is specious, since on another occasion it may be with hilarious mania that the calamity is met.

Moreover, the experiences of a lifetime will have determined what calamities are most felt; they need not be calamities in other people's eyes at all. Experiences, spread over years, are the common extrinsic cause of the more chronic neurotic forms of affective illness: this applies least to chronic hypomania. In these chronic conditions the patient's own behaviour has so much to do with what happens to him, as it were, from outside that to separate extrinsic from intrinsic is very hard.

**Pathology.**—The physiological changes are characteristic only of emotional disturbance, not of morbid emotional disturbance; and therefore they are not of

diagnostic value. They consist in lability of blood pressure and pulse-rate, abnormal motility of plain muscle, especially in the alimentary tract, carbohydrate disturbances, variations in either direction of the rates of salivary and other secretions and decreased psychogalvanic activity. The changes are variable from patient to patient and are not always discoverable. More significant are changes in basal metabolism, weight, sleep and menstruation; loss of weight is the rule during the illness. Irregularity of menses and then amenorrhœa often occur. Rise in the blood iodine content, changes in the K/Ca ratio, diminished cellular respiration, hypercholesterinæmia and signs of adreno-cortical hyperactivity have been alleged but not conclusively.

The *psychological* changes, in spite of great external differences, have the following in common: the morbid phenomena are in accordance with the prevailing mood, though not wholly derivable from it; thought is less purposively directed to impersonal ends than it would normally be, but more purposively to personal ones; there is a small number of topics of preoccupation in each patient, but his ways of arranging and embellishing them can be many; the whole body (or parts of it) often receives much of the patient's attention, because of more or, it may be, less feeling in it (hypochondria, depersonalisation); misconstructions abound, with consequent ideas of self-reference and persecution as well as misidentification; and there is a feeling of inner tension, unrest and excitement, however apathetic or carefree the patient's demeanour.

The seemingly greater quickness and capacity of manic patients has not been confirmed by psychomotor, intellectual and association tests; hypomanic patients sometimes, however, do better than in their normal state. This can be compared to the effects of increasing doses of alcohol. Patients with affective disorder are more irritable and excitable than is normal. Time appreciation may be grossly disturbed: personal time seems to pass very differently from clock time; time may seem to stand still; no future is conceivable. Perplexity may be conspicuous, and explanations of this in terms of Gestalt psychology, conditioned reflexes and toxæmia have been proffered.

The effects of experience in bringing about this illness cannot be explained in terms of a logical and coherent system, unless one accepts the premises of that system and infers what cannot be observed. Consequently, as there are several such psychological systems, there are several explanations. They state the conjectured ways in which instinctual energy or libido may become misdirected because of environmental conditioning, frustration and loss.

**Symptoms.**—**SYMPTOMS OF EXCITEMENT (MANIA).**—There is excitability of mood and movement. The *mood* is mostly one of jollity, rather infectious, but likely to become boring or overbearing; occasionally it turns to anger and resentment. It is labile; tears will flow readily on some trivial occasion, to pass into laughter in a twinkling.

*Thinking* is apparently rapid. There is flight of ideas, with successive words and phrases loosely connected only by similarities of sound or chance associations. Consequently, the patient wanders from the point; whether he can come back to it depends on the severity of his condition. Jokes, self-praise, flighty comment on his surroundings and facile optimism make up the tenor of his exuberant conversation. Nevertheless, the number of topics he touches on in the course of the day is often more limited than if he were in normal health: he reverts to a few matters over and over. He may criticise himself, with cynical bitterness or humour, as he criticises others; he may talk a lot about bodily disturbances, e.g. his varicose veins or his sore throat. His mood and expression are consonant with what he says. He is distractable, herein seeming at the mercy of his sensations and of every small detail, whether it be inside himself or, as is more common, connected with things about him. Judgement is impaired.

*Delusions* are less common than *distortions* and misstatements. People are wilfully

called out of their names, events misrepresented, bodily sensations exaggerated, and accusations of ill-treatment or persecution irresponsibly preferred and sometimes long persisted in. The more confused and excited the patient, the more likely to be deluded and even hallucinated. Most of the seeming hallucinations are *façons de parler* or illusions; sometimes the patient is, as it were, pretending or acting the part of a hallucinated person.

*Activity* is exaggerated, and in severe cases incessant. Its object may change from moment to moment, but sometimes the main end is kept pertinaciously in view. The patient, if tactlessly thwarted, gets angry, sulky or violent. He feels very strong, and seems untiring. He has many schemes, of an optimistic cast, and, in the course of putting them into action, may be extravagant, inconsiderate or interfering. Sexual excesses or drunkenness may occur and bring much harm, especially when the patient is a young woman. Troubles with the police arise through silly pranks or self-confident exploits.

*Sleep* is brief but deep. In the early and mild stages the patient looks exceptionally well, but after weeks or months of over-activity and little sleep he looks exhausted, with sordes on his lips, hoarse voice, drawn skin and perhaps less total activity but many unfinished little movements. Food is welcomed in the mild stages; when the activity is great, the patient does not give himself time to eat, but plays with his food or is continually diverted to something else. Sexual desire is at first heightened but potency less.

The symptoms vary widely in degree. Mild hypomania may be an enviable time of well-directed expansive energy, unencumbered by some habitual restraints; gross mania may be a delirious, hallucinatory condition, with incoherent talk and little free activity.

**SYMPTOMS OF DEPRESSION.**—In the early stages or milder forms, the patient finds concentration and recollection difficult, he has less interest and pleasure in life, he feels that this world is unreal and himself changed, he dreads effort or responsibility.

The *mood* is one of grief and misery, looking in every direction for material to feed on. The past supplies peccadilloes or graver lapses; what is wretched in the present is dwelt on inordinately; the future is foreseen as hopeless ruin. Anxiety is mixed with it, often in extreme degree. Weeping is less common in the extreme forms. The patient's expression usually conforms to his affect.

*Thinking* is more difficult. This "retardation" in thinking shows itself as incapacity to deal quickly and purposively with impersonal topics, while brooding on personal matters goes on, with a press of inner activity, a ceaseless roundabout of painful thought. The making of decisions is dodged. Conversation may become meagre, even monosyllabic, though some patients are ever ready to tell their troubles. The content of their thought is *sombre*—the product of ruthlessly unfair examination of their frailties and misfortunes. Some criticise themselves remorsefully or with cynical detachment; some bewail their losses; others abandon themselves to resigned and world-shunning despair. There are many varieties of misery, and melancholia knows them all—as many varieties as can be made from the experiences, character and imagination of a human being. Consequently they reflect the moral, economic or hygienic standards of what is good and bad that are imposed on us by modern society and our particular education.

*Delusions* occur in proportion to the depth of affect; they are the extreme form of the doubts or preoccupations just mentioned. Patients often fluctuate between uncertainty and conviction about their troubles even during the same day or the same conversation. Insight may be good and judgement sound, when the affect is not overwhelming. The delusions are the product of the depression, which is primary; they are not its occasion, though often adduced as that. Most of them concern the future as well as the past; anxiety is prominent. Wickedness to be visited with damnation; secular crime to be punished in this world; loss of property that will

mean starvation and beggary for one's family; mortal or corrupting diseases—these are the common substance of delusions and are often commingled. For example, some patients blame themselves for having caught venereal disease which will expose them to the loss of their job and of their hope of salvation, exclude them from decent society and do loathsome damage to their bodies; no evidence, no argument shakes the erroneous belief. The delusions may be grandiose in that the patient affirms himself the chief of sinners, no one has ever been as wretched or wicked as he, he alone has done the unpardonable sin; or they may be of a minimising sort—nobody cares about him, he is of no account, let him go into a corner to hide, people despise him. This last belief is often understandably associated with ideas of reference or persecution—people make contemptuous gestures or remarks as he passes, they set detectives to watch him, they tell each other how bad he is. He accepts this almost always as his desert, though occasionally there may be overt resentment. Apart from this resentment, his beliefs derive understandably from his affective state. There are, however, features that betoken undercurrents at variance with the professed attitude or delusions. Thus many depressed patients, professing humility, are importunate in their demands on those around them.

Such hallucinations as occur are in keeping with the patient's affect and are of much the same nature as the delusions, though expressed more in perceptual terms. People are making derisive remarks, his body gives off foul smells, food has a different and disagreeable taste—it is often the mode of expression rather than of subjective experience that decides whether these are hallucinations or delusions. This is notably the case with bodily preoccupations, when, for example, patients report their food to be stagnating in their belly, their skin dull or fetid, their eyes impaired, their head empty. Much of this depends on depersonalisation, in which the body as a whole feels bereft of life and feeling, and emotional deprivation or emptiness is translated into bodily experience. In mild forms of depression there is no question of delusion or hallucination, and often no recognisable content to the gloom; the patient cannot say why he is sad. In the more chronic forms a settled and partly justified conviction about ill-health, present troubles, and the dark future prevails; the ideas may be obsessional and partly divorced from the prevailing affect.

*Activity* is limited, thus contributing to the "retardation". The more severe the depression the less does the patient do, unless the concomitant anxiety makes him restless. It is possible, however, for a patient to be depressed without "retardation". In typical cases facial expression is rather fixed and movements delayed, as though done against resistance; more or less complex activities, dressing, say, or writing a letter, take unduly long. The most extreme form is stupor or lack of all spontaneous activity; it is seldom absolute. Patients rarely become wholly indifferent to cleanliness in defaecation and micturition.

*Suicide* is the greatest danger in depression. Whereas manic patients thoughtlessly do themselves harm or get into a fight but do not try to get hurt, depressive patients are often bent upon doing away with themselves. The risk is not proportionate to the degree of depression; many very retarded and melancholy patients make no attempt, while in depersonalised mild cases a fatal outcome is not uncommonly brought about thus. There is consequently much risk during the phase of improvement—often more risk than during the preceding severe "retardation". Deliberate self-mutilation is rare.

*Sleep* is bad—hard to come by, light and unrefreshing. The *appetite* is bad too: food may be constantly refused for this reason. Commonly also the patient eats too little because of feelings of fullness and other discomfort in the abdomen, or because of delusions about his bowels or his food. Mild constipation is common, but is often given much exaggerated importance by the patient. The *weight* diminishes, chiefly, but not wholly, because of insufficient intake of food. Daily fluctuation in the general condition, with improvement towards evening is common. The skin

may be dry and sallow, and in some severe cases pigmented, as it is in pellagra. Menstruation may lessen or cease; sexual desire is much less. There may be autonomic disturbance, generalised or limited to a single system.

Here, too, there are wide variations, between the mild "neurasthenic" and the grossly deluded melancholic who craves death. There is every gradation between the two extremes, and a single patient may during the course of the illness exhibit them all.

**SYMPTOMS OF ANXIETY.**—The *mood* ranges from uneasiness to panic-stricken terror. It may be an abiding or a recurrent state. Though chiefly turned to the future, as fear must always be, it rests on past experience, often painful and largely repressed, and it reverts to the past to account for the troubles in store. Herein, as with rationalisation and some other psychological devices, there is evident a strong desire to make things understandable in a causal nexus—a tendency to be found not only in patients but also in those who observe them. The patient's expression varies with the strength of his fear.

*Thinking* is troubled, the disorder showing itself in speech somewhere between frightened dumbness and the voluble talk that seems designed to cover up embarrassment and disquiet. The patient can seldom follow a train of thought for long without a limited number of preoccupations forcing themselves in. How far this interferes with daily life or set tasks depends on the amount of anxiety, as does also the impairment of judgement and insight. The content of thoughts is as manifold as in depression, every normal matter of human concern enters into it. Fears centring strictly on a few special topics, e.g. the fear of being run over in the street, may be to the fore; the fear of insanity is particularly common.

*Delusions* are frequent in the grosser forms, which are most strikingly though not exclusively seen in patients of late middle life. They may say that their bowels are stopped up and their bodies about to rot; their enemies are waiting to tear them to pieces; their families will be tortured; their names abhorred for ever. Hell, they are certain, awaits their souls though their bodies cannot die; time stands still and no redemption is possible. There are many delusions less extreme than these mainly hypochondriacal and nihilistic ones; e.g. beliefs that employment will be unobtainable, or that the patient will be victimised for having had such an illness. Hallucinations can occur: at the height of fear every sound and sight and smell may be misinterpreted as meaning some pain to come; but most of this is illusional colouring of actual percepts. Depersonalisation is common with all degrees of anxiety.

*Activity* is much disturbed. There may be sudden attacks of panic in which the patient rushes blindly out into the open, or aimless wandering, ceaseless agitation, with movements especially at the small joints—wringing of the hands, rubbing the face, picking at sores, pulling out hair. Starting many tasks and finishing none is as characteristic of anxiety as of mania. Anxious people are distractable: their eyes follow a trivial movement—a fly walking on the window-pane—though they only comment on it when some interpretation that chimes with their mood can be fitted; their ears are sharp for hints of alarm. During an attack of anxiety with strong somatic repercussions activity may be completely interrupted—so-called collapse—while the patient, terror-stricken, expects his death; alternatively he may run for air or help. Very agitated patients may lie or sit in semi-stupor, with starting eyes and parted lips, incapable of speech unless under some strong stimulus.

*Suicide* is uncommon in those with episodic, highly somatic attacks of fear, and in those with chronic mild hypochondriacal anxiety, but not infrequent in the grosser forms and in those mingled with depression.

*Sleep* is bad: in the mild forms the patient may be afraid to fall asleep because of his horrifying dreams and the terror into which he suddenly awakes.

Sudden highly somatic episodes of anxiety are common: the patient feels his

heart palpitating, his bowels turning over within him, he sweats, his limbs tremble, his mouth is dry, he feels he will fall or collapse or die; he turns pale, his pulse-rate changes, usually becoming more rapid, his blood pressure rises, he may want to open his bowels or pass his urine. When anxiety is long-standing and severe, such attacks are rare. It is possible for parts of this general affective disturbance to be isolated, and to occur with little conscious anxiety, as in muco-membranous colitis, effort-syndrome, aerophagy, neurotic indigestion, enuresis, impotence, ejaculatio præcox, psychogenic asthma, hyperidrosis. The factors determining such special emphasis on one or other system are partly physical (some organic defect or innate functional anomaly) and partly psychological. In anxiety thyroid enlargement can occur; weight falls off; menstruation is irregular or ceases; the deep reflexes are very active.

**Diagnosis.**—Typical cases are easy to recognise. The common errors of diagnosis lie in: (1) Missing organic disease (e.g. general paralysis, cerebral arterio-sclerosis); or the converse (e.g. mistaking the more expansive manic patient for a general paralytic). (2) Forgetting how mixed the symptoms of mania, melancholia and anxiety may be, so giving rise to atypical pictures that may be mistaken for schizophrenia, if too superficial an examination or too static and rigid a diagnostic criterion be used. (3) Forgetting the influences of age, general personality and milieu on the content of a patient's mind, e.g. his having lived among spiritualists may lead to deceptively fantastic statements. (4) Expecting to be able to diagnose solely on presenting symptoms, without regard to previous history and constitution; the reverse is also to be avoided. (5) Expecting diagnosis always to lie between distinct entities which could not possibly be mixed together in the same person, as though hysteria were incompatible with affective psychosis, or both of these with schizophrenia; in fact, they often are mingled. This is not to make light of diagnosis, which gives the psychiatrist much knowledge that he cannot gain from study of the individual case before him.

Nothing in the mental state of a patient with affective disorder may enable one to exclude an organic basis such as general paralysis or cerebral arterio-sclerosis. This decision must turn on the physical findings. The problem becomes simpler when signs of dementia supervene (see p. 1626).

From schizophrenia, diagnosis depends on a picture of the whole illness, on the presence of characteristic thought-disorder, incongruity of affect and bizarreness of behaviour, as well as on the previous personality and constitution, rather than on any positive features of affective psychosis; the remoteness and unconvincing manner of the schizophrenic, so hard to describe but almost conclusive when recognised, may help. Later, when complaints have become empty and repetitive to the point of stereotypy, and catatonic symptoms mix with the anxiety, diagnosis is easier. As between schizophrenic and manic excitement, the setting in which the excitement occurs is almost more important than the *prima facie* symptoms. In young people schizophrenic features may often be found without their being of much significance; in the elderly what seem to be catatonic features may rest on an organic cerebral basis. The more easily one can get in touch with the patient, enter into his mood and understand what he says and does, the more is it an affective, not a schizophrenic disorder. The range of benign affective phenomena is wider than a textbook description can convey.

There is no need, except for administrative purposes, to try to diagnose affective psychosis from psychogenic depression, cyclothymia, anxiety neurosis, neurasthenia, or involutional melancholia; these are only subdivisions of it, in which the age of onset, reactivity, severity or chronicity of the condition is being stressed. Periodic recurrence is sometimes made the hallmark of affective psychosis; this historically interesting point of view is hard to apply, because so many patients have only one definite attack in their lifetime, and because periodicity can be striking in other conditions, such as obsessional disorder and schizophrenia.

From obsessional disorder the diagnosis may be difficult when there is localised anxiety or depression with sharp content and good insight; so closely alike are the conditions, that some authorities have proposed to include obsessional disorder also in the manic-depressive group, thus disposing of the diagnostic problem. It is best, however, to keep them distinct, and to discover in a particular case whether the characteristic subjective rejection of the obsession occurred at its first appearance; often the anxious or depressive patient at the beginning has accepted the thought which accords with his affect, though later he struggles against it and may disclaim it. Genuine obsessions, however, are common in affective psychoses.

**Course and Prognosis.**—The varieties of outcome and sequence are many. They depend on the balance between particular intrinsic and extrinsic causal factors in each case, and on the extrinsic factors which are brought to bear on it in the form of treatment. The more typical the illness, the surer the recovery in favourable circumstances.

A history of definite affective psychosis in a parent or grandparent points to recovery from the attack, but it is unsafe to infer the course of the illness from hereditary data alone. A well-adapted personality and a pyknic build, a history of similar illness followed by complete recovery, a fairly sharp and fairly recent onset, and precipitation by external troubles which will not be likely to continue are all of them points to the good. Advancing years make the prognosis poorer, but a first attack of melancholia in late middle life, if there be no vascular disease, eventually clears up in two-thirds of the cases; convulsant treatment has further improved the prognosis for this group. Bodily changes are often the best indication of coming recovery. Improved appetite and regularity of the bowels, cessation of anxiety symptoms, clearing of the complexion, increase of weight and return of menstruation may be noted, even before any increase of activity and long before any admission of feeling better can be got from the patient.

A first attack of excitement or anxiety will seldom be the only one; of depression it may. Periodic depression and anxiety is less likely to cease in middle life than periodic excitement. The occurrence of hallucinations or delusions is in itself of little consequence prognostically. A transition from anxiety to depression or mania, and from mania to depression, or vice versa, is commonly gradual. Only in predominantly reactive attacks can one surmise how long the illness will last, or when another attack is to be feared. After recovery complete insight into what happened during the illness may not be attained, especially by resentful manic patients, melancholics who are sensitive and suspicious, and agitated patients who feared personal harm.

**Generalised somatic disturbances, e.g. loss of weight, especially if acute and brief,** are of good prognostic import, other things being equal. The more the somatic preoccupations or symptoms are diffused over a period of time and localised to one system, the poorer the prognosis; this, however, does not apply so much to children as to adults. Hypochondria and depersonalisation suggest a long illness, as do nihilistic delusions (e.g. hystering that one's bowels are opened at all), and, to a far less extent, admixture of hysterical or schizophrenic features. The more the psychogenic causes have been obviously operative for a long period, the greater the tendency to chronicity. In the more chronic forms or after a series of attacks, there may be impaired initiative and judgement, irresoluteness, dullness and social deterioration—none of them conspicuous. Puerperal and pregnancy psychoses have a good outlook. The milder forms of anxiety and depression, if not already chronic, respond well to treatment, especially to psychotherapy.

Death may occur from suicide, insufficient food and intercurrent disease, especially pneumonia.

**Treatment.**—**PROPHYLACTIC.**—Genetic prophylaxis is occasionally possible, as when two persons with definite affective disorders marry each other and are advised

not to have any children. Rules of thumb do not apply in this matter; it is wrong to tell a patient he should marry or not marry, procreate or not, unless one has been able to weigh the dubieties of our genetic knowledge, the pedigree of the patient and all his transmissible qualities with an informed and cautious judgement.

Individual prophylaxis is not usually practicable until after symptoms have appeared which bring the patient to the doctor; social prophylaxis and child guidance may, however, have value in staving off or mitigating affective illness, especially in those who are temperamentally very responsive to adverse circumstances, *e.g.* in their domestic life, their upbringing or their employment. No satisfactory evidence is forthcoming that such measures can forestall the grosser affective disturbances, necessitating mental hospital care, which occur in highly predisposed persons. In so far as one finds that environmental factors (*e.g.* heavy responsibility, unemployment, or sexual frustrations) have been important in provoking an attack, advice on these matters may be helpful; it may be practicable by psychological and social treatment during the healthy interval to do much good in this way. But some cases, in which intrinsic factors seem all powerful, are proof against such measures, and in any case it is not easy to persuade the patient when he is well again to put himself for a long time in the doctor's hands.

**TREATMENT OF THE ACTUAL ILLNESS.**—It is convenient to consider separately the acute major forms, and the minor more chronic cases.

For the former, the treatment other than by convulsions is directed to safeguarding life, relieving distress and providing the best conditions for the emotional disturbance to subside; the situation is like that in tuberculosis or typhoid fever. Exhortations to "pull yourself together" are as out of place as advice to take a voyage or an argument about the delusions. If the attack is sufficiently severe to unfit the patient for ordinary duties, treatment at home is probably inadvisable. Although in such attacks all argument is futile and active psychotherapy harmful, yet the loss of relation between current experience and emotion is never absolute; there is virtue in separating the patient from real trouble and distressing associations, reassuring him, giving him firm, kind management. The essential combination of these, and especially the last, is rarely obtainable at home. The patients, however boisterous or suicidal, usually recognise their need of treatment and are willing to enter hospital voluntarily. They should not transact any business if it can be helped; their judgement may be too much disturbed, they lay up trouble for themselves. Continuous narcosis sometimes curtails an attack; it demands experience and care.

Convulsant treatment is valuable; most of all for involutional conditions, least for mania. Among involutional patients those with baseless suspicion and resentment respond less well than the self-reproachful and agitated. It is still uncertain how much benefit can be obtained in younger patients with acute affective disorder; many of the figures purporting to show that in manic-depressives (thus distinguished from involutional melancholics) the recovery rate after convulsant treatment is also high, have been compiled from a series of patients the majority of whom had reached later middle life and might therefore have been properly classified as involutional. It is, moreover, difficult to evaluate recovery rates for this purpose in a condition in which recovery is often obtained by other therapeutic methods, such as would probably have been employed along with the convulsant treatment. Whereas in the depressive conditions of late middle life there can be little doubt about the general superiority of convulsant treatment to any other available method, in the affective disorders of earlier life it is only by the effect on the duration of the attack, and the subsequent frequency and severity of attacks, that the efficacy of convulsions can be judged; the restricted information available does not give any conclusive general answer, though it is evident that, on the one hand, some young patients have their attacks of depression promptly cut short by this method of treatment, whereas previous attacks not treated thus had lasted for many months, and on the

other hand some of them soon relapse. For manic patients it is on the whole disappointing.

Convulsant treatment by the electrical method has superseded chemically induced convulsions. It is important that the psychiatrist should not use subconvulsant doses if he can help it. The number of fits required varies from patient to patient but it is unwise ever to give a total of more than twenty fits. Patients with circulatory or pulmonary disease should only be allowed to have convulsions after the risks have been fully weighed. In order to lessen the chance of spinal or other fracture, a relaxant is administered, usually in conjunction with barbiturate intravenously.

For the depressions of middle life convulsant therapy has enough success to justify calling it a specific method of treatment. By the electrical method, fits lasting less than a minute are induced three times a week; not more than ten fits are usually required. A relapse may necessitate repetition of the treatment. Fragile bones or vertebral deformity may preclude use of the method, unless special precautions are taken and the dangers made known to the patient or his responsible relative. The treatment should not, except in very special circumstances, be given as an outpatient procedure. It is capable of causing temporary, and perhaps permanent cerebral damage, though, as a rule, the forgetfulness or disturbance of consciousness which may follow the fits soon clears up. In spite of the simplicity of the actual procedure—hardly more complicated than turning on the wireless—the tiro can do great harm with it by selecting patients who are unsuitable on either mental or physical grounds, by giving too many or too few fits, and by neglecting methods of preventing fracture and other complications.

Patients with severe and long-standing agitated depression sometimes are much improved by frontal leucotomy; the longer they have been ill the less good is the operation likely to do.

Prolonged baths—for 8 or 10 hours daily at a constant temperature of 96° to 98° F.—have much value in allaying restlessness, whether of the manic or the anxious kind, especially the former. They have the further merit of diminishing angry contact with other people, permitting fairly free movement and lessening dirtiness, besides promoting sleep.

*Drugs* are indispensable. The fear of habit formation should not prevent hypnotics being given when there is persistent insomnia. Barbiturates or paraldehyde often suffice: it is well to ring the changes and to diminish the dose without the patient's knowledge. For severe anxiety opium (e.g. as papaveretum) and hyoscine may be helpful; the risks are obvious. Continuous narcosis is valuable, but must be used with caution. Food must be given in adequate quantity and kind. The induction of mild hypoglycæmia by insulin each morning may be helpful in inducing a willingness to take more food. Artificial feeding, preferably by nasal tube, may be necessary because otherwise the patient would die of starvation. The presence of acetone in the urine and a falling weight curve are strong indications that nutrition must be attended to promptly. A good nurse may sometimes, by unusual patience and sense, get over an obstinate refusal to take enough food and drink, but often nothing prevails against it. Apart from hydrotherapy, rest in bed, fresh air, attention to the bowels and other measures of general hygiene are desirable.

*Suicide* is of the first importance. Prevention of it can be better ensured by close knowledge of the patient and his day-to-day condition than by mechanical precautions, but if he is bent upon it, these may be unavoidable. It is possible to make them unobtrusive without nullifying them. Certain it is that excessive use of bolts and bars can defeat its own ends, and excessive supervision aggravate a patient's misery, his fears or his resentment. Two good rules are: (1) to discredit the maxim that those who talk of suicide never commit it, and (2) to remember that most suicides are surprises. Convalescence from melancholia is a risky time.

Occupational therapy is good, as soon as the patient can be got to co-operate;

but it is not rational treatment to pester a melancholic, to encourage the fretful restlessness of the agitated, or to give the manic patient more things to muddle himself with and destroy. Still, it is often surprising to find how soon, under tactful guidance, these patients will enter into ordered activity of a more or less simple sort, and how helpful it can be to them. During the stage of improvement the same is true of recreations and social activities. Patients should not leave hospital till recovery is assured, unless it is obvious that the hospital surroundings and the absence from home and work are an actual cause of their persistent anxiety or dejection.

To revert to the *milder* forms, which tend more to become chronic. Here manipulation of the conditions in which the patient lives at home and at work may be conjoined with psychological treatment (individually or in a group), depending on an appraisal of the causes of his illness. There is nothing distinctive (though much that takes account of the individual patient's needs) in the psychotherapy and social treatment called for (see pp. 1618, 1619); danger signals must be recognised as they occur. Zeal must give way to the real needs and resources of the patient, which are often not appropriate to a drastic or very lengthy treatment. Simple measures of enquiry, explanation and reassurance, together with small environmental changes, may have much effect. A fixed régime imposed in detail by the doctor is helpful; this becomes more and more necessary as the affect dwindles in long-standing cases. Hypomania does not usually respond to causal treatment of any kind; it seems to run a largely autonomous course. Anxiety may yield very satisfactorily to patient psychotherapy and environmental adjustment.

## SCHIZOPHRENIA

**Definition.**—The forms of illness under this name are so diverse that many efforts have been made to distribute them, so far in vain. What is common to them all is a detachment from the world without, and a breaking up of normal psychological connections within. The personality is not integrated as in normal people; thinking, emotion and conduct are discrepant and morbid, yet there is no impairment of formal intelligence such as is found, for example, in organic dementia. The obsolescent name "*dementia præcox*" is not a synonym for schizophrenia, but a reminder of its recent history. At the end of the last century a large number of patients in mental hospitals were found to have begun their illness before they were 30, and to have passed ultimately into a deteriorated state that looked like dementia; their illness was closely studied, delimited and called "*dementia præcox*". When the same clinical picture, however, came to be found in cases that had not such an outcome or onset, the latter criteria were waived in favour of a descriptive analysis of the actual symptoms, and along with this larger conception came the new word "*schizophrenia*", which betokened a more psychological approach, and a more elastic and generous notion of what might be included. Theories of causation, psychopathology and clinical boundaries are implicit in any view of what "*schizophrenia*" really is; consequently, it is still possible for two experts to disagree about what should properly be included under this name, yet over the diagnosis and prognosis of any particular patient they will attain a measure of agreement and certainty surprising to those who know the condition only from reading or limited experience.

**Ætiology.**—**INTRINSIC.**—The intrinsic factors are very important. Studies of the incidence in twins and in the members of a family demonstrate a hereditary factor in a majority of cases. If one of a monozygotic pair of twins be schizophrenic, the other is also in 76 per cent. of cases, whereas the corresponding percentage among dizygotic twins is only 14. The nature of the mode of transmission is still in doubt; the most recent observations suggest a single recessive factor which must be inherited from both parents. Variations in the manifestation of the disorder may be in part

dependent on a non-specific character controlled by a multi-factorial genetic mechanism.

The constitutional features that betoken an innate predisposition to this illness are more of the psychological than the physical kind. The bodily attributes have been said to be an "asthenic" or "ectomorph" (weedy and lank), "athletic" or "dysplastic" build; but, since these are found in much the same proportion among healthy people as among schizophrenics, and the correlations between habitus and diagnosis are not convincing, there is little to be said for them here. It is, however, certain that "pyknic" build (see p. 1646) is uncommon among schizophrenics. More significant, however, are the features of personality, commonly called "schizoid"; they are to be found in a large number of cases, though not by any means in all. The patient is reported to have shown slight peculiarities from his earliest years; he has been quiet, shy and solitary, a "model child", given more to daydreaming or abstract speculation than to ordinary interests and activity; sometimes he has been unduly submissive and sentimentally affectionate, or touchy, suspicious, obstinate, and resentful of advice and control. A single "typical" schizoid personality is a myth. It is, moreover, to be stressed that a "frozen" description of the schizoid varieties of personality does not do justice to the true state of affairs: characteristic deviations from the conventional norm of behaviour can always be understood better if the patient's way of dealing with his circumstances is viewed historically as a biography of individual tendencies and experiences, rather than described as a bundle of traits. By paying heed to the development of faulty as well as healthy habits of response, the psychiatrist can often see the march of events that led up to the patient's illness, and escape too artificial a sundering of inherent tendencies from the external happenings by which these tendencies have been evoked and given shape and substance.

**EXTRINSIC.**—The illness sometimes breaks out after childbirth or an acute infection. None of the efforts made to inculcate some specific infection have succeeded, nor has intoxication in general been found to play any considerable part in the causation of schizophrenia. The same is true of cerebral trauma. There are, however, many instances of a chronic schizophrenia supervening on an intoxication, and of schizophrenic symptoms, especially of the catatonic sort, appearing in the course of an organic disorder, such as G.P.I. or encephalitis lethargica. In these, the same structural and functional systems must be supposed to have suffered impairment as in the "endogenous" forms of schizophrenia, and it has been particularly urged that in the chronic paranoid conditions that may follow an acute alcoholic psychosis, it is really a matter of schizophrenia that happens to be associated with alcoholism, if not partly activated or released by it. It is further to be remembered that certain intoxications, *i.e.* with mescaline, lysergic acid or adrenochrome, produce a mental disturbance that is in some respects similar to schizophrenia, and that any chronic hallucinosis comes in time to look very like a long-established schizophrenia, probably because the possibilities for abnormality of any human mind are few, the deprivation symptoms almost uniform, and our methods of clinical examination imperfect. Endocrine disorders, especially of the gonads, have been held responsible, but are more probably manifestations of emotional disturbance; findings are not consistent and the relation between endocrine and psychological events still rather obscure.

Recent mental stress may sometimes be the starting point of an attack, but in a considerable proportion of these cases the reported overwork, disappointment in love or other painful experience, is found to have been a product of the already existing illness, or the last of a long series of disturbing events. No recent experience is ever sufficient to account for the illness without regard to intrinsic causes. Nor is any remote experience either. No matter how searchingly the patient's life be resurrected and analysed, it is scarcely ever possible to discover that anything happened to him which would have led to his adopting a schizophrenic way of shunning daily life unless he had been somehow disposed to it from the beginning; although, of

course, much may have happened to him that has strengthened and fostered the disposition.

Among contributory factors, age and sex are noteworthy. An onset after the age of 40 is uncommon. In three-quarters of the cases that later exhibit the characteristic chronic syndrome, the illness begins between 15 and 25. The condition may become overt in children before puberty. Men are more often affected than women—in the proportion of 113 to 100, according to the largest available statistic; the matter is dubious, however, because of the different standards of diagnosis used.

**Pathology.**—**PHYSICAL.**—Histological changes in the brain are not characteristic; it is doubtful if they are even frequent. A cellular loss in the third and fifth layers of the cortex, with lipoid accumulation, has been found, but it occurs in many other conditions. Swelling of the oligodendroglia has been described in brain tissue obtained at biopsy. Many claims about cerebral pathology, and the chemical and physiological changes in schizophrenia have now been discredited, so that all findings in this difficult field have come to be matters of suspicion. Variations in the same individual may be wide. Investigations have purported to show: a disturbance of the acid-base equilibrium towards the acid side, with a diminished excitability of the respiratory centre to carbon dioxide; lowered rate of oxygen consumption; polyuria; diminished gastro-intestinal motility; poor response to epinephrine, insulin and dinitrophenol; and to vestibular stimulation by cold water or rotation; abnormal heat regulation; abnormally variable sugar, creatine and non-protein nitrogen content of the blood; anomalous capillaries; decrease or sluggishness of total blood-volume; and slowing of the arm-to-carotid circulation time. These findings, indicative of a defect in adaptive capacity, have not so far been controverted; they represent disorders of metabolism and regulation which may be partly a concomitant of the characteristic mental disorder, and partly an effect of it, *i.e.* they may be essential physical disturbances in the illness, or may be secondary to the abnormal, often inert, life the patients have led since they became ill; thus evidence of hepatic dysfunction in catatonic patients is of nutritional origin and may be corrected by changing to a suitable diet.

Some inferences have been drawn from the similarity of catatonia to the extra-pyramidal syndrome that can be produced in animals by bulbocapnine; the argument from analogy cannot be pushed further than to say that certain functional systems are available in the brain, disorders of which are sometimes evident in schizophrenia, as they also may be in poisoning or in encephalitis lethargica, G.P.I. and other diseases.

Very significant are the well-attested metabolic findings in the rather rare cases of cyclical catatonia. In these the nitrogen balance varies periodically; with alternating phases of retention and over-excretion, corresponding to the mental change from excitement to stupor or vice versa. By means of thyroxine a thorough emptying of the patient's nitrogen store can be brought about and subsequent nitrogen retention prevented, thus leading to clinical improvement. The correlation between metabolic happenings and clinical condition in these patients is now established.

**PSYCHOLOGICAL.**—The large and inconclusive literature on the psychopathology of schizophrenia derives from:

- (1) Minute description of the phenomena observed, and abstraction from them of general principles of disordered function.
- (2) Experimental study, using projective, sorting, reasoning and other tests, as far as possible under controlled conditions.
- (3) Studies of artificial hallucinoses (*e.g.* mescaline intoxication) and parallel experiences.
- (4) Comparative study of animals, children, poets, primitive people, etc.
- (5) Intuitive or speculative interpretation.

It will be obvious that these methods overlap and that they differ widely in

acceptability and usefulness. The findings of almost all can sound plausible, when stated in general terms; discrepant or abstruse, when stated in detail. Their exposition touches on the most intricate problems of normal and morbid psychology, and therefore is highly technical and unsuitable here. A working hypothesis for clinical purposes is that in schizophrenia there are inherent faulty dispositions, whose manifestation depends, in severity and persistence, on upbringing and other external circumstances. It is characterised by, among other things, a perversion and failure of synthesis, so that there is an inco-ordination, "intrapyschic ataxia", as it were, a splitting up of the mental life, which justifies the name "Schizophrenia". The whole psychic life of the patient, cognitive, emotional and conative, may be changed in a way that is alien to normal understanding. We can observe the change but to enter into it or describe it adequately in terms of our own experience is far more difficult than if we try to do this for depression, manic excitement, hysteria or obsessions. It shows itself also as a turning away from the contacts and realities of daily life, a preference for what the mind can supply from its own stores, however, morbidly, rather than for the current experience that the outer world affords.

**Symptoms.**—Schizophrenia may be regarded for clinical purposes as a form of maladaptation in which there are characteristic defects of inner harmony and consistency in behaviour, thought and emotion. These are rarely seen in childhood, but from puberty onwards they may appear in varied combinations (often in persons who for years have been introspective and unsocial). There is discrepancy between mood and utterance, disturbance of conduct (briefly summed up as catatonic or hebephrenic), self-absorption and incapacity for sustained thinking along normal lines. A guarded or artificial demeanour may conceal these essential features, whereas they may be conspicuous in a florid or "deteriorated" case. Hallucinations and delusions may fill out the picture; affective or other morbid types of reaction may complicate it.

The onset is not always abrupt. There is often a long history of preliminary symptoms in which it is arbitrary to decide where personality has merged into illness. Complaints of headache, weakness, anxiety attacks, loss of appetite and dysmenorrhœa may have accompanied slight oddities of behaviour, such as rudeness or apparent absence of mind and indecision. The patient may have felt an alarming change in himself, in his capacity to think and feel normally, and been notably depressed and anxious. Ideas of persecution or of exaltation may occasionally escape him, or he may have become stilted in his talk and shown other affectations and mannerisms. The more gradual the onset—and in many cases it has spread over many years—the more unlikely is it that it will have been recognised as morbid.

The commonest or basic symptoms are: (1) Disorder of thinking. (2) Emotional incongruity. (3) Hallucinations. (4) Disturbed impulses or conduct. From these can be derived most of the other symptoms, such as delusions, feelings of influence, autism, catatonic phenomena, anomalies of speech, negativism and the rest.

The *disorder of thinking* is a characteristic and central feature. The patient cannot command the whole range of an act of consecutive thought; he misses the point, fastens on details and brings in irrelevant associations which are correct in themselves, but which divert him from the main end of his original process of thought; consequently his thinking is incoherent, rambling and jumbled. He brings together the most far-fetched topics, so that the connections are sometimes so superficial as to be empty of meaning, and at another time profoundly influenced by symbolism and highly individual values. The usual logical sequences are ignored: cause and effect are interchanged; temporal, spatial, verbal and accidental relationships are unduly turned from abstract to concrete, treated as grounds of identity, played with or flouted. Things linked only by analogy and chance association are taken to be the same. The condensation of several conceptions in one, or transference of a set of attributes to some inappropriate object, may become a matter of course, so that only the closest knowledge of the patient and his surroundings will enable the psychiatrist

to follow his meaning. It is not necessary, however, that such extreme incoherence be evident in the patient's talk; he may not show any at all when speaking, or may suddenly obtrude a startling lapse from normal ways of thought which he then ignores, justifies or explains away. Inconsistent thoughts can be present together in a way impossible for normal people; and the same object or notion can appear to him in several interchangeable guises, each of which would normally exclude the others. The patient himself is often aware of his disordered thinking, and may describe it: he feels his thoughts are suddenly taken out of his mind, other thoughts, foreign to him, are put into his head, his mind is not his own, his thinking is suddenly interrupted, some external power controls it.

The thought-disorder is illustrated by the following characteristic remarks of patients: "There were bats and bees coming through the window; of course that was because my brother-in-law kept teasing me. He said I had bees in my bonnet." "If I should return during my absence, keep me here until I come back." "I have a lot of forced thoughts. My thoughts are all drawn-out words, they ought to be pin-pricks. There is an unnatural stoppage in my thoughts, too. . . . I have heard voices say, 'He is conscious of his life' . . . To get my feeling back to normal I feel like changing motor-cars into battleships, to be superior to them."

This disorder may only be demonstrable when the patient gets on the topic of his delusions; in other matters he may seem quite sensible. It is not essentially different from what normal people experience during states of altered consciousness, e.g. in dreams, or when falling asleep; the schizophrenic, however, has it with clear consciousness, so that a listener often feels that the patient is making fun of him in giving such transparently absurd answers with an air of knowing exactly what he is about. A chronic well-preserved schizophrenic has been known to make his living as a comedian, the audience much enjoying the allusive, half-comprehended nonsense, with its background of innuendo and symbolism. Autism, i.e. immersion in his own fantasies and preoccupations, may account for much of the oddity and detachment the patient shows; it accounts also in part for his "negativism", in that he resents any stimulus that interferes with his daydreams.

Delusions arise mainly out of the thought-disorder. They are often bizarre; they may occur to the patient with a suddenness of conviction that puts them beyond all argument; and they are egocentric in that they commonly bring indifferent happenings or people into a special relationship with the patient—e.g. he suddenly knows that when his cousin yesterday said he had been reading about Napoleon's divorce of Josephine, it was a subtle way of telling the patient that his wife was committing adultery with this cousin, whose name is Joseph. The delusional ideas may not be firm conviction, but fleeting notions, readily given up, and based upon some casual instance of the thought-disorder; sometimes they are schizophrenic ways of saying something commonplace—e.g. the patient declares his wife has poisoned him, but when he is further questioned says airily that he means she gives him ill-cooked food which is bad for his digestion.

Fixed delusions are, however, common, and are usually of a paranoid complexion; they may develop out of more or less ephemeral ideas of reference. They are often intermixed with hallucinations. The patient gets into a state of mind in which he feels there is meaning in everything, something is going on behind the scenes, he is perplexed by all this, and mystified, it has to do with him in some uncanny way. Presently, he begins to "see through it all", sometimes he gives it some religious or cosmic significance, especially if he has much anxiety as well—the Last Judgement is at hand, he is to be responsible for the regeneration of the whole world. The delusions are not always enacted on so grand a stage; there may be homely fancies about neighbours who whisper and sneer, or about some bogey like the Jesuits or the Jews or the C.I.D. Often, the patient complains that people work on his mind, hypnotise him, influence him for his own good, set about to drive him mad or ruin

him. Delusions of grandeur may be linked up with these paranoid ones (e.g. he is being persecuted because he is the Messiah), and may be likewise pedestrian or lofty, according to the patient's previous education and interests, the severity of his disorder, the copiousness of his fancy and the amount of normal mental function still in evidence. Here, as elsewhere in psychiatry, the symptoms are a mixed outcome of impaired or perverted function on the one hand, and of normal function on the other, the latter either reacting to and modifying the disorder, or obtaining freer play through it. If, for example, a patient feels his thoughts being controlled by some external influence, and he has queer tinglings in his body, his conviction that he is being hypnotised, and that someone is playing an electrical instrument on to him, must be regarded as a normal attempt to find the cause of an almost inexplicable happening. The delusions are sometimes about past events, which are falsified retrospectively, e.g. the patient relates details of his having been a changeling or a predestined hero. Delusions about bodily transformation or disease are frequent, and may be complicated and bizarre.

Patients often do not act in accordance with their delusional beliefs, especially when these are fleeting or chronic; they may, for example, be friendly towards a nurse whom they believe to be persecuting them cruelly. But this is, on the whole, unusual in the early or acute stages of the illness: a patient will then act on his beliefs violently or in terror; he may go to the police or be driven to suicide.

Constantly the matter of a patient's delusions will be found to be intimately dependent on his experiences, his emotional attachments and sufferings, his struggles and frustrations; it is impossible, however, by any such analysis and derivation of his delusions to account for the fact of their occurrence, i.e. for the patient's choice of this way of dealing with the experiences in question. The same is true of the general thought-disorder: e.g. interruption or "blocking" of the train of thought may take place only when some emotionally weighted topic, some complex, is touched on. This accounts for the place where "blocking" occurs, but not for the "blocking" itself; that, like the other fundamental disturbances of function in schizophrenia, eludes a wholly psychological explanation.

Intellectual defect does not occur, though the patient may find it difficult to form concepts necessary for abstract thinking. There is usually no clouding of consciousness. Intellectual laziness or evasion is often conspicuous; the patient may repeat questions in a musing way, or profess ignorance. Orientation and memory are not, as a rule, diffusely impaired, though hallucinations, delusions and lack of interest may interfere with them, and consciousness may be disturbed in stupor or excitement. Many a patient who has long borne the appearance of gross dementia will suddenly show that his intelligence is still a sharp instrument: drugs, e.g. sodium amytal or insulin, and intercurrent disease or shock can thus dramatically reveal how little ground there is for calling this illness a dementia. Schizophrenics often do the unexpected. Amnesias, and deliria, when they occur in schizophrenia, may be hysterical; obsessional and hysterical symptoms, like anxiety and depression, are compatible with schizophrenia, and are often an intimate component of the illness.

The speech and writing of the schizophrenic betray the extent of his thought-disorder. Stiffness, pedantry, fantastic euphuisms, words of his own coining, queer symbols and grammar, stereotyped repetition and infantile twists like speaking of himself always in the third person may be conspicuous features of the patient's use of language. There may, of course, on the other hand, be little or nothing outwardly amiss in his conversation and writings. In florid or chronic cases the patient may talk in an unnatural voice, or without any modulation. Writing may be set forth as though it were painting, and the converse: in subject and matter the patient's insanity may be patent, but his treatment of his matter, however odd, is seldom odder than some forms of art, and it cannot be called typical of the illness. These anomalies of symbolical representation are as open to psychological explanation as are the

delusions mentioned above; the neologisms, for example, can be analysed up to a point; and these phenomena have enriched our knowledge of the psychopathology of schizophrenia.

The *emotional incongruity* is the chief, but not the only, sign of disturbed affect. Often the patient himself notices in the beginning of his illness that he is less moved by habitual affection, or even feels hatred towards a parent he has loved. The strongest and rarest of human passions are not infrequent in this illness: ecstasy, mystic communion, despair, horror, agony of death, limitless abandon, apotheosis, salvation, are approximate names for these exceptional states that are probably indescribable in the current language of normal people. Apart from these, and much the commonest of the affective changes, is apparent emotional shallowness: the patient receives moving news without any sign of being touched by it, or his response is perfunctory; he smiles or looks bored when talking of a recent tragedy in his own family. This shallowness and incongruity of affect is, however, not to be taken at face value. What the patient says, and what he means with his words, may be very different; so may what we say be very different from the meaning the patient attaches to it. It is unsafe to assume that the patient's words have reference to what is mainly going on in his mind at the moment, or that his outward expression is a trustworthy index of his emotional state. Violent emotional outbursts—of anxiety, rage, love, misery—can certainly occur in a patient who has lately seemed empty of all affect. The schizophrenic patient is undoubtedly different from normal people in his emotions, but not in so negative a way as his seeming apathy and lack of affective rapport would suggest. His attitude towards the same person may change quickly, in accordance with conflicting or opposite tendencies in himself; this ambivalence is often understandable in the light of his earlier history. Sometimes the illness leads to a blunting of ordinary reserve, a lack of reticence, or a levelling down of the gravest matters, so that frivolous or cynical indifference and imperturbability are signs of the patient's morbid condition.

*Hallucinations* are not so frequent as superficial examination of patients might suggest; many of the patient's assertions about queer sights and sounds are not the expression of vivid perceptions but of passing fantasies, imagined more plastically than is normal; this is particularly true of many of the so-called visual hallucinations, or of cases where the unreal perceptions occur in several senses together. Hallucinations are nevertheless extremely common and persistent in schizophrenia; auditory ones occur most often, diffuse somatic ones not infrequently, those of smell, taste and sight more rarely.

The "voices" are sometimes so closely linked with the thought-disorder that it is difficult to tell whether the patient is relating what he has heard or what he has thought. He may show the intermediate stages between the two, declaring that people repeat his thoughts or that everything that passes through his mind is spoken aloud inside his head; his actions are described publicly, he cannot go to the lavatory without shameless comments. What the voices say may be abuse or encouragement, trivial repetition or threats and commands; this content can usually be accounted for by the psychiatrist, when he knows the patient and his history well. The voices may come from strange places, *e.g.* from inside the patient's own chest or abdomen, and are then often accompanied by curious somatic hallucinations, indicative of morbid attitudes, both physiogenic and psychogenic, towards parts of the body. The latter often occur independently. Queer sexual feelings, or distortions and impossible growth of various organs, may be reported. They are usually bound up, as any schizophrenic symptom is likely to be, with delusional and emotional components, which are partly derived from the patient's experiences and psychological development. The visual disturbance, like the gustatory, is more often illusional than hallucinatory, *e.g.* people's faces look fiendish or artificial or transfigured.

The *actions and bearing* of the patient are often characteristic. Abruptness or

lack of grace in movement may be seen early; it can be indistinguishable from the fidgety self-conscious hobbled-boy stage of adolescence. The patient may pull faces at himself in the mirror, or may be unaware of his grimaces. Asymmetrical movements of expression, twitchings, mannerisms, queer rituals and tic-like gestures are to be met with. The meaning of the patient's movements can usually be worked out, but after they have been present for long their sharpness is rubbed off, as it were, and the empty stereotyped movement at last gives little clue to what was once a significant emblem of experience and feeling. The movements often seem to become automatic, like the "verbigeration" of empty phrases in the patient's speech. Negativism, talking and acting beside the point, and bizarre escapades may be seen at any stage of the illness.

There may be a suspension of movement, or the reverse: akinesia or hyperkinesia. Both may occur in the same patient, who may lie for weeks or months in a catatonic stupor, from which he suddenly emerges into swift action. He may carry out some impulsive action and then promptly return to bed and stupor; or he may become wildly excited and imperil his life by his blind and raving activity. During catatonic stupor, patients may adopt strange postures, e.g. holding their head off the pillow all day, pursing their lips. They may be indifferent to cleanliness about faces and urine, or actively dirty in this regard. Waxy flexibility is rare, but many patients are automatically obedient so that they keep up an imposed posture.

The variety of schizophrenic anomalies of conduct is too great to be described here. They must not be assessed absolutely, but always in relation to the setting in which they occur. Then they have meaning in the individual case, and are not merely so many examples of "ambivalence", or "mutism" or "negativism". It is, however, true in this matter also that understanding the content of an anomaly does not make its occurrence likewise understandable. Much of the schizophrenic's conduct is so close to certain disorders of movement in organic disease of the central nervous system and its connections, that somatic mechanisms may be assumed to have suffered damage in this condition. There are three main things to be done with any schizophrenic symptom: (1) to search out its psychological origins, and its meaning for the patient in his present situation; (2) to link it up with the other functional disorders that he shows and (3) to consider its background of physical structure and function. It is not always practicable to attempt all three, nor is it as yet possible to do them well, but none can be ignored without detriment to a full analysis.

Often the most significant yet intangible effect of the illness is upon the patient's personality. After florid symptoms have died away, or when there are no definite symptoms at all, a change in the patient's ways is remarked by his intimates. Not only is he outwardly different—more "peculiar", less understandable and predictable, rather shut-in upon himself, remote, with queer values and impulses—but in many cases he is also aware of this change, and may complain of an inner perversion of himself, a loss of that unity which we take for granted when we say "I", or "me". Insight in schizophrenia, in this respect and more generally too, may be penetrating and just, as many self-descriptions attest. There may also be varying degrees of impairment up to gross lack of insight.

None of the bodily symptoms are characteristic of this illness, though many occur. Besides the somatic complaints and preoccupations already mentioned, patients, especially if young, show vegetative anomalies. Thus, vasomotor disturbance may take the form of cold bluish extremities, exanthems or oedema. Seborrhœa is common. Abnormal growth of hair occasionally occurs in women. Loss of weight in the acute stages, and fatness in the chronic condition, interruption or irregularity of menstruation, and fluctuations of temperature may also be observed, especially in catatonic cases; of the schizophrenic states, stupor is the richest in demonstrable bodily changes. Fleeting neurological signs, e.g. pupillary anomalies, may be found.

In states of acute excitement attacks of unconsciousness may occur, but epileptic seizures are very rare.

**VARIETIES.**—There are three main forms—catatonic (with acute outbursts); hebephrenic and simple (early onset, chronic course); paranoid (fairly late onset, delusional). They are not exclusive categories, and it is usually profitless to try and apportion a doubtful case to one of the other. They do not correlate closely enough with outcome or effective form of treatment to be of much use clinically.

In *hebephrenia*, the least common variety, delusions and hallucinations are inconsiderable, but abnormal conduct is to the fore: the patient may be silly and mischievous, abruptly eccentric or inert and without initiative. The illness may progress without acute episodes ("dementia simplex"), or be interrupted by phases of excitement or obvious insanity, which subside, leaving the patient worse than before. In *catatonia*, the most favourable variety, the symptoms are plain even to the layman: akinetic or hyperkinetic states may appear and subside quickly, sometimes for good or for several years. There are usually, also, characteristic disorders of thought and emotion, which may clear up when the stupor or the excitement does. In the *paranoid* form, generally rather late and insidious in its development, but less damaging to the personality than the hebephrenic, partial systematisation of the delusions is common in the earlier stages, but may be later swallowed up in the general thought disorder and deterioration ("dementia paranoides"). The more bizarre the delusions, the more likely is affective emptiness to replace gradually the initial resentment and distress, but sometimes the patient passes into a chronic paranoid state, obviously schizophrenic to the psychiatrist, but compatible with ordinary life outside an hospital. Hallucinations and luxuriant delusions may, however, be conspicuous in the paranoid form (paraphrenia and "dementia phantastica").

**Diagnosis.**—The chronic and advanced cases—"typical dementia præcox"—that abound in mental hospitals, are easy to diagnose: but early or inconspicuous cases often extremely difficult. The chief positive points to look for are: characteristic thought-disorder, a qualitative change of affect, and other evidence of "intra-psychic ataxia", as well as feelings of being under external influence. Catatonic symptoms are of limited diagnostic value, because of their frequency in organic and symptomatic psychoses. More important than any single feature is the impression of the cases as a whole, the development away from normal interest and response to the real world, and the establishment, instead, of "autistic" self-satisfactions so that the patient's personality is twisted awry, as it were, and withdrawn from easy contacts.

It is unsafe to lay much weight on the diagnostic help afforded by projective and other psychological tests. The intuitive element in the interpretation of Rorschach and other findings of this kind is greater than is consistent with a reliable diagnostic procedure. The psychological data may suggest schizophrenia but should not be the decisive factor.

From organic syndromes—syphilis of the central nervous system, alcoholic psychoses, disease of the cerebral vessels, encephalitis lethargica, etc.—the differentiation turns on the physical findings, more than on the mental state: a schizophrenic syndrome may appear in an organic condition, because the brain, as Kraepelin said, is like an organ whose stops give out the same sound, whoever works them. Often it is not a matter of deciding whether the syndrome is organic or schizophrenic, but whether, being schizophrenic, it has a discoverable somatic basis or not. Alcoholic delusional states are an instance of the complicated relationship that may be found (see pp. 1638, 1639). If, after consciousness has become clear again, the other phenomena of toxic confusional psychosis persist, then schizophrenia is the more probable diagnosis.

Diagnosis of schizophrenia from an affective syndrome is difficult, because both are often combined in the same patient. Some of the significant points have already been referred to (see p. 1652). Catatonic excitement differs from mania in

that the speech and acts of the latter are intelligible as expressing a general affect and are conformable to the situation in some measure; the onset and cessation are not so abrupt as in catatonic excitement; and there are usually characteristic features which make the distinction easy. Melancholia becomes suspect when delusions are repeated without the appropriate effect, and there is a readiness to project responsibility for the illness, to complain of external influence. The inertia of the depressive is not so complete as that of catatonic stupor, nor so likely to be abruptly broken through. States of severe agitation are not always easy to distinguish from schizophrenic excitement, but a more frequent problem is that of deciding whether some bodily fear or conviction of disease is schizophrenic or not. Whether in regard to a preoccupation or a delusion, the chief point to consider is the appropriateness of the affect to the alleged hypochondriacal notion; the more bizarre the bodily change described, the more likely to be schizophrenic. Depersonalisation is sometimes at the bottom of these somatic complaints; what is significant is not the depersonalisation, but the way it is elaborated and regarded by the patient.

*Hysteria can offer great difficulties, largely because hysterical mechanisms are so often operative in schizophrenia.* Plain motor or sensory disturbances commonly give less trouble than hysterical dissociation, stupor and pseudo-dementia. The previous history, the relationship of the outburst to a particular set of happenings, the behaviour in the intervals, the demands upon the attention or response of bystanders must be taken into account. The mistakes and oddities of the hysterical pseudo-dement may be theatrical, in accordance with his ignorant notion of what insanity is like; the deliriously dissociated hysteric does not identify correctly the people around him, as the schizophrenic usually does, even when in a dream-like state; the hysteric who is acting some imagined scene does so without discrepancies or gross interpolations, whereas the schizophrenic is seldom so consecutive and persistent. The degree to which the patient is being influenced by his immediate surroundings is, however, the chief guide, apart from definite schizophrenic features.

*Obsessional states offer difficulty when the patient is in doubt as to whether his alien thought or impulse comes from within his own mind or is imposed upon him.* If he shows indifference as to the occurrence and content of the compulsive ideas, it is suggestive of schizophrenia; but careful examination of the development of the symptom, and the patient's attitude towards it, permits a clear diagnosis in most cases. Complicated rituals, odd obsessions and chronicity make an obsessional illness look very like schizophrenia; as does intoxication of an obsessional patient by bromides. Obsessions may develop into schizophrenic symptoms (see p. 1679).

*Prognosis.*—Schizophrenia is always a serious condition. Though some recover, the tendency of this morbid change is to do permanent damage to psychic life. In the individual case, however, pessimism is not justified. It is certainly never possible in the early stages of the illness to be certain that recovery is out of the question.

*Heredity is a poor guide to the prognosis, except in the rare cases in which an identical twin of the patient has for some years had a schizophrenic illness, or in which one parent is schizophrenic, and the other has schizophrenic relatives; even then it is difficult to prognosticate with assurance regarding the present attack.* If one parent has had an affective illness the prospects of recovery are brighter, but this can better be assessed from the patient's own bodily and mental constitution. If he is of pyknic build, the outlook is much better. Similarly, the patient who has for years tended more and more to withdraw from his surroundings, to be careless of social requirements, to lie late and live alone, given up to day-dreaming and eccentricity—such a one should be become overtly schizophrenic, has a poorer chance of doing well than the active, suspicious and impulsive man, or the self-conscious, introspective worrier who similarly falls ill. A narrow and rigid previous personality makes deterioration more likely than if there had been wide interests and possibilities of adaptation.

The more abrupt and stormy the onset, the better the outlook. This is one of the most reliable guides. When the onset has followed upon a recent painful experience, and the content of the patient's talk and his behaviour refer to this, or when a physical damage appears to have provoked the symptoms (*e.g.* influenza or head-injury), the outlook is rather better than when the provoking factors are obscure; but this is by no means always the case. If the attack occurs during puberty or adolescence, prognosis must be cautious, because of the difficulty of distinguishing between the transient upsets of this period of adjustment, and the progressive schizophrenia that may then show itself plainly. The earlier history is of great help.

The nature of the symptoms is not a safe guide. Very severe departures from normality may clear up, yet an outwardly mild condition be of grave omen. Symptoms such as stereotypies of movement and speech, which indicate that the illness has been going on a long time, and that there is a general narrowing and fixity, are grave; as are also hebephrenia, and a long-drawn-out stupor, with negativism, impulsive violence and vasomotor changes. The more manic or depressive features, the better. Previous attacks, with an interval of normality between them, are prognostically favourable. If the patient first falls ill after 30, he will scarcely go downhill in the tragic way young people sometimes do. He may develop fixed delusions, which are often rigid and encapsulated, so to speak, and therefore he may be able to return to ordinary life, with reservations; or it may be that his morbid beliefs absorb all his mental powers, and compel institutional life. The more the psychiatrist can discover healthy modes of response in the illness itself, as well as in the previous personality, the happier the outlook. Many patients, after an attack, do not return to work, but have narrower interests, and less spontaneity than before; they are more easily tired, and may be hypochondriac, or show other symptoms thought to be "neurotic". Such patients have sometimes made a poorer recovery than others who return to work and can meet most social demands, though careful enquiry reveals definitely schizophrenic sequelæ in their thinking and emotions.

The simplest rule is that an abrupt onset of the illness, an adequate cause for its occurrence and a well-adapted non-schizoid personality are the criteria of good prognosis. Sensible early treatment may avert disaster.

**Treatment.—PROPHYLACTIC.**—This, whether eugenic or individual, is limited and uncertain. Even if effective, it can reach only a minority at present, and its effectiveness is a matter of faith. Probably child guidance and other measures of mental hygiene do good in averting potential schizophrenia, but no one can be sure of this. Such treatment aims at diverting the child into social activities and keeping him out of situations in which he will be mortified or otherwise troubled emotionally. However wordily or abstrusely the prophylactic treatment be described, it is essentially a matter of trying to make an unusual child into an average one, or changing his surroundings to suit him.

**TREATMENT OF THE ACTUAL ILLNESS.**—There is no one treatment of the disorder that has manifest superiority over any other. Insulin has striking results in some early cases, but is neither a specific nor a panacea. Painstaking attempts at readjustment of the patient's outlook and behaviour by means of suitable psychotherapy, occupation, games, etc., are the most systematic and rational ways of making a permanent change for the better. The co-operation of the patient is here necessary, and also the help of a social worker desirable, who may do much to modify and arrange the patient's circumstances in the interests of his mental health, *e.g.* getting him suitable occupation, and schooling his relatives in a sensible attitude towards him. Such treatment is not practicable for those acutely ill, but for the mild, the convalescent or the imperfectly recovered case it is of great value. By means of it many patients can be discharged from hospital before they have settled into apathy, or become unresponsive to the claims of the external world; it is better not to keep a schizophrenic patient in hospital waiting for complete recovery, but to get him back

into ordinary life as soon as possible, provided conditions there are not too adverse for him, or he too abnormal to cope with them.

Treatment in a psychiatric clinic or mental hospital is usually necessary at some stage of the disorder, and must be decided chiefly by the severity and social risks at the time. For the large number who become permanently in need of institutional care, much of the deterioration formerly customary may be averted by the energetic use of occupational therapy and recreation which make the patient's life less sterile. The term "total push" has been applied to a programme having this object, and attaining its social end in proportion to its vigour in using all available means of stimulating and encouraging the individual patient.

There are few conceivable ways of altering a human being that have not been tried in this illness. Many of them have been those believed to be efficacious in other illnesses; some have been intended to shock the patient somehow. Of the former may be mentioned thyroid and other endocrine preparations (in large doses), transplantation of gonads, removal of supposed septic foci, induction of fever by malaria, etc., injection of human serum, manganese salts, production of aseptic meningitis, hypothermia and continuous narcosis. Of the latter, *i.e.* shock-methods, many of the procedures of a bygone time are examples; the whirling chair, precipitation from a height, immersion in ice-cold water and so forth. The most recent methods which entail a profound disturbance are those which use insulin or a convulsant (see p. 1621). The convulsant method has been of value in some acute stupors and conditions in which, along with the schizophrenia, there is a considerable affective admixture.

The value of insulin treatment is variously assessed; some believe that it should be given to every schizophrenic as soon as his condition is recognised, others that it benefits those who would get well with other forms of treatment, if administered with equal zeal. The former say that it shortens the duration of illness and increases the number of recoveries; the latter insist that this improvement is seen to be largely spurious if a "follow-up" enquiry is made into the later course of the patients' lives. That such extreme views can be held by responsible observers relying on large series of cases is due, not only to their prejudice and temperament, but to the difficulties of judging therapeutic success in an illness which is sometimes difficult to diagnose with certainty in its early stages, is often accompanied by another more benign mental illness, and has anything but a uniform prognosis; moreover, it was believed to be hopeless by many psychiatrists in pre-insulin days, so that they did not try to treat it by methods then available which would have yielded full permanent recovery in a quarter of the cases, if selected on the same basis as is now customary for insulin treatment. It was the general experience before the advent of insulin that a third of the schizophrenic patients who were admitted to an active psychiatric hospital within a year of the onset of their illness got better with general treatment and remained capable of life outside a hospital; mass figures from a heterogeneous collection of psychiatric hospitals showed less satisfactory results. This partly accounts for the discrepancy between those who report remarkable improvement in the proportion of schizophrenics who recover now that insulin has been used for their treatment, and others who cannot discover any statistically recognisable difference in efficacy between conservative treatment and the insulin method, under comparable conditions of case-selection and management. An additional cause of discrepancy in results lies in the different methods of administering insulin treatment. Some aim at giving the lowest dose of insulin that will produce coma, others prefer the highest dose that can be given without endangering the patient's life; some let the comas continue for 3 or 4 hours, others terminate them earlier, and there are even advocates of comas protracted up to 15 hours for patients unresponsive to milder measures; hypoglycæmic convulsions are regarded by some as therapeutically valuable, by others as harmful. Insulin and convulsant treatment have demonstrated beyond dispute

that in the present state of psychiatry the value of a new therapeutic procedure should be assessed not by the reports of enthusiastic pioneers, invaluable though their efforts and observations are, but by the outcome of a planned therapeutic trial in which uniform standards have been employed in the selection of cases, the method of administering the treatment and the assessment of outcome; also due regard must be paid to the choice of those "control" cases with which the beneficiaries of the new method are to be compared.

The insulin method consists in the induction of hypoglycæmic coma daily, for not longer than 3 months. It is seldom desirable to exceed sixty comas. The coma is allowed to last a variable period, according to the clinical condition. If unduly prolonged, it may be difficult to terminate it by the usual method—the administration of carbohydrate through a nasal tube or intravenously. Persistent or "irreversible" coma is the chief danger of the treatment; about a sixth of those who pass into such a state die. Because of this and other complications, mostly avoidable, the insulin method should only be used by experienced persons, in a hospital adequately organised and staffed for the purpose. The treatment is most effective in cases which would have a good prognosis for the attack if treated by other methods. In a series of more than a thousand patients treated with insulin, 13 per cent. recovered and were still well 2 years later, at which time there were also 14 per cent. much improved. Such figures are so much influenced by the choice of patients that they cannot easily be compared with the results of other methods. In the main, however, they speak in favour of the insulin method, if applied with discrimination, skill and willingness to use other methods also, during the administration of insulin or afterwards. Frontal leucotomy has been employed in otherwise intractable cases, and some patients thus treated have become easier to look after or fit to leave the mental hospital.

The details of treatment, whether in hospital or at home, must be individual; even in such matters as the allaying of excitement no uniform procedure, *e.g.* continuous baths, or narcosis, can be a routine measure. When excitement is extreme, disturbances in water metabolism and loss of salts may be combated by giving 5 per cent. saline intravenously, 300 ml. every other day, alternating with forced fluids. During stupor, general measures for ensuring adequate food (in some cases feeding by tube), cleanliness and evacuation of urine and faeces must always receive attention. It has been found that various chemical agents, such as carbon dioxide inhaled in a 30 per cent. mixture with oxygen, and sodium amytal, will temporarily interrupt a catatonic stupor; this finding accords with the metabolic changes reported in the condition, but its therapeutic value is slight.

## PARANOIA AND ALLIED STATES

The words "paranoia" and "paranoid" are used loosely by many. Kraepelin gave paranoia its modern meaning, describing it as the endogenous, insidious development of a permanent and unshakable delusional system, with complete preservation of clarity and order in thought, will and action. If the illness cleared up, if it showed symptoms of an organic, affective or schizophrenic syndrome, or if it was provoked by external happenings, it could not be paranoia. Thus delimited, the condition is exceptionally rare; so rare, indeed, that there is no use in having such a category. Moreover, cases that Kraepelin himself called paranoia have since become obviously schizophrenic. The same is true of paraphrenia. There is now no profit in thinking of paranoid states as syndromes in their own right, so to speak, and of the same order as schizophrenia or affective disorders. They are on the same subsidiary level as stupor, hypochondriasis, anxiety and depersonalisation. When met with, they must be distributed according to the accompanying symptoms and the

general trend of the illness; and their prognosis and treatment must be assessed accordingly.

Besides the paranoid beliefs and attitude referred to in previous sections, there are a number of instances of this unhealthy relationship between the patient and his surroundings, which may be mild in their outward form, easily understandable in the light of the patient's history and fairly responsive to treatment. Some deaf people become distrustful, misinterpreting what they cannot hear plainly, and construing it into a jeer or an insult. Sensitive and shy people are often troubled by doubts and shame as to their physical or moral worth; and, by projection, attribute to others the dislike or contempt they do not acknowledge in themselves. This occurs in youths who masturbate, and suppose others to remark it, and in old maids who believe men to be pursuing them; but there are many varieties of shame and desire, besides the sexual, which lead to such ideas of reference or persecution. The development of paranoid reactions of this sort is usually plain. So is that of the querulous, resentful type of reaction, e.g. in the man who believes himself done out of his rights and who becomes a persistent litigant or writer of memorials. Before judging such a man psychopathic, the extent of the injustice he has suffered must be compared with the degree of his resentment and his relevant conduct. Commonly the injustice is found to be fanciful or trifling, and the man's sense of grievance immoderate, so that he comes to believe there is a veritable conspiracy to wrong him, and devotes most of his time to useless appeals or threats. He may persuade his wife or his children of the justice of his complaints, inducing delusions in them, *i.e. folie à deux*, etc. Many such patients, however, never become deluded: they are contentious about their wrongs, and waste years, perhaps, in proclaiming them or seeking redress, but they are well aware how other people regard them, and what has actually happened. Many claimants of compensation, "grouzers", "old soldiers" and unstable adherents of more or less cranky movements, are to be placed here. There is no sharp dividing line between these psychopathic people, and the more or less normal, often socially precious, leaven who detest injustice and are willing to do much to defeat it.

## HYSTERIA

In hysteria, symptoms of illness are represented by the patient for the sake of some advantage, without his being fully conscious of this motive. The form of representation will vary widely according to the circumstances that have provoked the illness, the patient's experience of what the symptoms are that he is trying to represent, and his somatic resources. These factors, presently to be discussed, bear on the hysterical symptoms that simulate physical disease. But it is impossible to restrict hysteria to this physical form. The illness that is represented by the hysteric may be a mental one; moreover, it is not possible to consider hysteria without regard to the mechanisms of its occurrence which manifest themselves in the personality and are mainly psychological. Hysteria is the most psychogenic of all illnesses. Its recognition is therefore a double problem: (1) exclusion of what may be called "genuine" illness, *i.e.* of a recognised morbid pattern and (2) discovery of an adequate motivation. To ignore either of these requirements is to court error, since hysteria may occur along with physical or mental disorder, elaborating upon it and mimicking it, and, on the other hand, some physical diseases give rise to symptoms indistinguishable in their form and apparent psychological mechanism from those of hysteria.

**Ætiology.**—A hereditary factor is probable in many cases. Thus, a group of hysterics who were pathological liars were compared with the average population in respect of the proportion of their brothers and sisters who were in mental hospitals: it was five times as many; and of the parents of the group, a sixth were psychopathic. From these and similar figures it is not possible to tell the mode of transmission or

the nature of what is transmitted, but only to infer a hereditary factor. The occurrence of hysterical mechanisms in children, and their frequency in healthy adults, especially after calamities or in unendurable conditions, such as may occur in war, suggest, however, that hysteria is potentially present in most people and that environment is more important here than heredity. The combination of heredity and environment may result, long before actual illness occurs, in a *hysterical personality*. This is not found in all patients who show hysterical symptoms, but nearly all people of hysterical personality show hysterical symptoms. Many of the features of this personality are socially obnoxious, but other features are not, and it is wrong to use "hysterical" as a depreciatory epithet for a set of qualities that one dislikes. These people are unduly responsive to the situation they are in, especially if by their excessive response they can fulfil wishes of which they are hardly aware, or evade what is painful in the situation, instead of meeting it and disposing of it adequately. Unsatisfied with their own capacities, they seek to cut a better figure than their endowment warrants, and are constantly posing and pretending. This, like all their behaviour and aims here described, is not done with full consciousness, but with a more or less sincere ignorance or ambiguity of purpose; it is not a question of deliberate deceit, of studied histrionics or malingering. In thus responding to situations and turning the response to some inadequate end, the hysterical person is characterised by a lack of inner stability and of constant standards of behaviour, and also by a lability of affect and an exuberant fancy. The fantasies normal in childhood are here seen in physically mature adults, who, like children, can temporarily live their fantasies, absorbed in this unreal compound of past experiences and longings, yet not so wholly divorced from their real surroundings as might appear. In an attenuated form, this is evident when they almost unwittingly manufacture some situation, according to their needs—literally "making a scene"—and enter into it emotionally with a rapidity and fervour impossible for more stable people. Egotism and untruthfulness (*pseudologia phantastica*) may be pushed to the point of delinquency. There may be a longing for prestige, sympathy, love or some other emotional relationship, which leads the hysteric to behave in a way strikingly out of keeping with his demeanour on other occasions; the inappropriateness of his behaviour even at the time may be obvious to a detached onlooker, but is not always so. Many of these people can use illness or well-acted fantasies of illness to satisfy their hardly conscious needs; they may also gain their ends by forgetting what it would be painful to remember. Here again the onlooker may find it hard to tell how genuine or complete is this forgetfulness, but the question is of little moment compared with discovery of the motive for the hypomnesia. Hysterics are often regarded as unduly suggestible because they respond so readily or violently to situations and to people with whom they develop an emotional relationship, often unrecognised by themselves as such. The emotional attitude of a hysteric towards others is often influenced by sexual factors. Hysterical personality is believed to be commoner in women than in men, and may be associated with psychosexual immaturity. Coquetry and frigidity are not uncommonly allied in hysterics; there may be much flirting and sexual excitation, stopping short of coitus. It is, however, juster to say that the sexual lives of hysterics show instability and inadequacy than to specify any particular aberration.

Hysterical personality can be recognised before puberty; in younger children, however, it must be extreme to be recognised, because of the great frequency of such mechanisms normally then (e.g. behaving as though fantasies were real, counterfeiting illness, somnambulism). Some of the grossest instances of hysterical behaviour have been recorded in girls not yet adolescent, *cf.* the Salem witches. Much of the work of child guidance clinics is taken up with the treatment of hysterical tendencies, not perhaps taking the form of definite symptoms but plainly evident in the child's personality.

The precipitating factor for the onset of hysterical symptoms is usually a situation,

emotionally charged, out of which the patient's symptoms will bring him more or less overt, but unacknowledged, gain. This gain need not be material and obvious, and may run directly counter to such accepted values as health and ability to work. One of the plainest instances of a partial unsubstantial gain is that created by an injury, and the resulting insecurity and claim for compensation or pension; hysterical symptoms flourish in such a soil, and are usually influenced for the worse by repeated medical examinations. Hysteria occurs among soldiers under active service conditions, and can readily be fostered in them by injudicious measures.

**Pathology.**—This is almost wholly a matter of psychopathology. It is true that disseminated sclerosis and many other organic diseases of the brain may be accompanied by hysterical symptoms, but the association is not a constant one. The psychological changes can usually be traced further back than the happening that provoked the illness; often they are the continuation of normal tendencies of childhood that have been fostered and extended by ill-judged upbringing. The hysterical symptoms that appear as motor or sensory phenomena show the patient's readiness for the translation of experience into bodily symbols; this is a special instance of the universal tendency for somatic representation of experience, converting it into action. It is the facility and exaggeration, not the existence, of this "conversion" mechanism that is characteristic of hysteria. What is thus translated or "converted" into physical terms has been something painful and unacceptable; the partial exclusion of it from consciousness, "repression" of it, is therefore understandable; in its physical, symbolic form it is tolerable and may even be prized. Identification with other people is responsible for the frequent imitation of symptoms and for the epidemics of hysteria. Clearly the mechanism need not be limited to the production of physical symptoms, though bodily structure and local weaknesses may conduce to this. There can be hysterical phenomena, such as the dissociation seen in fugues and so-called splitting of personality, which are instances of the exclusion of recent and remote painful experience from clear consciousness. The wishes and fears that deviously attain outward expression as hysterical symptoms do not derive solely from the recent past, though much of their strength may come from it. It must be admitted that there are some hysterics in whom this psychopathology cannot be demonstrated, and that such cases are among the most intractable.

**Symptoms.**—These may be divided into: (1) sensory; (2) motor, including fits and (3) quasi-psychotic.

The symptoms can be like those of any conceivable affection of which the patient has a notion. The cruder his notion, the less will his symptoms be like those of the simulated condition, but after he has been demonstrated to a class or repeatedly examined he may better his notion, and consequently his symptoms come closer to those of organic disease. Or, if he has had opportunity of seeing insanity, his pseudo-insanity may smack less of the stage than it otherwise usually does. The range of hysterical symptoms is so great that to describe them all in detail would take inordinate space, and there is no need to do so.

The sensory or, more properly, the *perceptual* symptoms include *clavus* and *globus hystericus*, blindness, deafness and *anæsthesia*. The two former are so common in all sorts of mental disorder, especially those accompanied by anxiety, that they are of little specific importance in hysteria; enquiry as to their presence will often in these rather hypochondriacal patients lead to their occurrence. The difficulty in swallowing reported by hysterical women may be associated with a strong disinclination to eat—*anorexia nervosa*; it should not be confused with depressive *anorexia* or that of pituitary *cachexia*. Any cutaneous disturbance of sensation that the patient has a notion of can be presented, *e.g.*, *anæsthesia*, either *mono-* or *bi-lateral*, or of stocking and glove distribution, and *analgesia* of any part. The *anæsthesia* seldom corresponds to any nerve trunk, nerve root, or spinal segment, unless the patient has had special opportunities of knowing. With an *anæsthetic* hand objects may be

identified, and any test which the patient does not recognise as referring to this disability he will perform satisfactorily. Such tests are not a means of "catching the patient out" as though he were a malingerer, but of ascertaining whether the symptoms express only his notion of some illness. The tests for a malingerer, it is true, amount to the same thing, though one assumes the malingerer to be clearly conscious of his purpose; consequently any distinction between hysteria and malingering must depend on the observer's impression as to the patient's honesty and self-knowledge; certainly it cannot be decided by tests. The tests for blindness (*e.g.* using a stereoscope with a supposedly blind eye), deafness (*e.g.* effect on pulse, respiration and psychogalvanic reflex of exciting remarks addressed to the patient), and for other forms of perceptual defect all depend on the physician's greater knowledge of what should or should not accompany the symptoms of which the patient complains; they are not intended to discover hysterical "stigmata" or characteristic anomalies. The ovarian and other hyperæsthetic spots, the pharyngeal anæsthesia and the concentric limitation of the field of vision formerly used diagnostically, were all products of suggestion or, as in the last instance, phenomena that may occur in normal fatigue, in hypochondria and in certain cerebral lesions.

The motor symptoms are paralyzes, pareses, spasms, contractures and tremors. Hysterical paralysis or paresis never affects individual muscles, but always movements. By various devices it can be shown that the patient can still use the affected muscles, as long as he does not know that the movement in question requires their use. The paralyzes affect chiefly the left side of the body, are common in the legs (preventing proper walking or standing), and often occur in limbs or other structures that have earlier been the seat of an organic disability, *e.g.* trauma or paresis. If the paralysis be flaccid, no loss of tone or of reflex response is found, and the patient, through his ill-informed notions of what should happen, behaves otherwise than a patient with organic paralysis would—*e.g.* if asked to rise from the supine to the sitting posture, without using his hands, he keeps his paralysed leg flat on the bed. If the paretic part be kept stiff, the antagonists will be found to come into action first when the patient is asked to perform the movement he says he cannot; and if the movement has to be made against resistance, sudden removal of the resistance reveals how much of the apparently tremendous effort was going into associated irrelevant or antagonistic movements. Passive movement to overcome the spasticity or subsequent contractures cause the patient to be more upset than could be accounted for by any pain he may complain of. The varieties of abnormal gait are numerous; many of them fantastically elaborate and, from the look of them, exhausting. Not only the musculature of the limbs may be affected but of the trunk (leading to curvatures and odd postures) and indeed any voluntary muscles, *e.g.* of the tongue, larynx, pharynx or eye. In hysterical aphonia the voice may sink to a whisper, or there may, more rarely, be complete mutism; the voice can, however, be used normally for coughing and similar purposes. The aphonia often comes on after some local inflammation that has caused hoarseness, or after a fright. Stammering, usually of the exaggerated kind, may also occur. Spasm of the external ocular muscles, leading to a convergent squint, may accompany a spasm of accommodation. Ptosis and blepharospasm sometimes occur. Many of the tics and spasms that used to be thought hysterical are now recognised to be often physiogenic, *e.g.* residual symptoms of encephalitis lethargica and chorea; spasmodic torticollis, for instance, is far less often psychogenic than used to be supposed. When a spasm or paresis has long been maintained, trophic disturbance may follow: blueness and œdema, shiny skin, fibrosis of periarticular structures and similar effects of rigidity and disuse. Tremor may occur and is often gross, as in many of the war cases. It is variable in degree and rhythm, and often disappears when the patient's attention is turned from it; this, however, is not a safe criterion.

Hysterical fits commonly occur in patients with obviously hysterical personality.

responded to psychotherapy. Psychogenic fugues are not invariably hysterical; they may be symptoms of a reactive depression in which despair and perplexity are conspicuous.

"Pseudo-dementia" covers the large group who behave as though insane. It may occur, as in the so-called Ganser syndrome, in prisoners awaiting trial. Whatever the circumstances, its motive is escape from a disagreeable situation. It is likely, however, that it is mainly those with a predisposition towards severe mental illness, especially schizophrenia and the high-grade defectives, who have recourse to this kind of hysterical behaviour. It sometimes comes on after brain injury. The patients' behaviour corresponds necessarily to their notion of insanity, which is usually far enough removed from anything the psychiatrist knows as such. Occasionally, however, it is very near the buffoon-like conduct of some schizophrenics. The patients say that they do not know their own age, affect not to understand simple remarks, give absurd answers which nevertheless indicate that they know the right answer (e.g. by inverting the correct order of the figures in a sum). When asked about some simple matter, they look as though they were making terrific efforts to remember (herein behaving differently from the schizophrenic). The most characteristic thing is the disparity between the patient's alleged deficiencies and his general alertness; he says he does not know anything about his own past, he cannot read or spell or do the simplest arithmetic, and yet he may be behaving quite naturally and adapting himself to the situation in a way which would be inconceivable if he had actually so advanced a dementia.

Some hysterics go to great lengths in their representation of ideas of illness. They will allow themselves to be put among grossly insane people, or submit to repeated operations, such as amputation. Self-inflicted injuries, e.g. keeping wounds and sores open, are not uncommon (cf. dermatitis artefacta). In some such cases masochistic tendencies can be recognised, but by no means in all. Suicidal attempts are not infrequent. They often have as their purpose revenge, the satisfaction of some spite, and the patient may leave behind a lying, fantasy-coloured letter, indicting someone. Frequently the suicidal attempt is in the nature of a theatrical demonstration, carried out in such circumstances as make it unlikely to be fatal; and if the patient kills herself, it is more through bad management than intention.

**Diagnosis.**—It will be plain from what has been said that diagnosis must be both negative and positive—negative, by excluding any organic cause for the symptoms; positive, by finding motives and relating the symptoms to them. Neither method is alone sufficient, because of the occasional concurrence of structural disease with psychogenic symptoms. As to the former, i.e. the negative method, it is unnecessary to enter here into all the differentiating points. Many of them have been mentioned in the foregoing description of symptoms, and all turn on the disparity between what experience tells us would occur if these symptoms were of organic origin, and what the patient knows about such matters. Consequently a doctor who has hysterical symptoms is extraordinarily difficult to diagnose, in this negative sense. The method of arriving at a diagnosis by suddenly taking the patient unawares, and seeing if his symptoms persist, is to be deprecated; it antagonises him. Likewise undesirable is the procedure of seeing whether one can suggest new symptoms to the patient.

of some physical disease. It is, however, in neurology that the most difficult cases of all arise, e.g. in disseminated sclerosis, carbon monoxide poisoning, cerebral vascular disease or encephalitis lethargica; here there is more likelihood of the organic disease being overlooked than of its being wrongly diagnosed. The patient's previous personality, any provocative situation or emotional disturbance, the previous occurrence of organic signs, e.g. transient diplopia, and the age of the patient must be considered. Hysterical symptoms appearing for the first time in middle or later life in someone whose personality has been stable, are probably not solely psychogenic. If the symptoms diminish when little or no attention is paid to them, they are more likely to be hysterical.

**Course and Prognosis.**—This depends mainly on the patient's personality and social setting, and on the treatment employed. A long history of hysterical traits prior to the illness, a continuance of circumstances favourable to the symptoms and inadequate or excessive treatment are all unfavourable. This is, however, an illness that sometimes confounds prediction, patients recovering when many adverse factors have been operative and the symptoms have been present for years. In children the prognosis is fairly good if treatment can be undertaken promptly; it is best if the hysteria is monosymptomatic and has come on after a fright. In all cases in which the situation which provoked the illness persists, the outlook is bad; for example, in compensation cases for which no medical treatment is of any avail—for obvious reasons—until the litigation is settled once and for all. Similarly, during war, psychotherapeutic successes are often dazzling while the hysterical soldier is under treatment in hospital, but the symptoms come again when he must return to duty. There are many varieties of outcome, chronic invalidism being the commonest. A few patients later become schizophrenic, and a few become involutional melancholics. The prognosis in respect of the patient's hysterical personality is more important than that of his hysterical illness; it is, however, no more to be assessed by rules than the general future of any human being's life and personality. Patients do not necessarily tend to become anti-social; delinquency is certainly a likelihood in some hysterical people, but bravery and self-devotion may be conspicuous in others.

**Treatment.**—Too much treatment is worse than too little. Injudicious physical or psychological treatment of hysterics often makes their symptoms worse and their illness intractable. Recondite methods should be eschewed by all but experts. Common sense is as important as psychological understanding; and social usefulness more to be aimed at than removal of symptoms or attainment of self-knowledge. In short, it is not the hysterical illness or the mechanism of repression and conversion that calls for remedy, but the patient's inadequate way of dealing with difficult situations. Consequently, the whole treatment must aim at the patient's return to ordinary conditions of life as soon as possible, and at a re-education of his ways of meeting difficulties. To this end it is profitable to go over with the patient the situations, emotional disturbances and motives that led up to the illness, and to do this without implying moral judgement or social indifference—certainly without teaching the patient one's psychological theories. It is a matter of general psychotherapy (see p. 1619); and it may entail a far-reaching analysis of the patient's past life, her emotional development and her instinctual tendencies. It is questionable, however, whether anyone without special psychiatric experience is wise to enter lightly upon this way of benefiting the patient. For, on the one hand, he may be misled into a wilderness of fantasy masquerading as once-repressed, now-recalled psychic trauma; and, on the other, he may be at a loss how to deal with the attachment and dependence upon him which the patient will come to show, and which may in fact be the chief influence in bringing about her precarious recovery. A great deal may be achieved—perhaps as much as by more thoroughgoing methods—if the physician, himself mature and with impartial insight into the psychological motivation of the symptoms, leaves aside in his dealings with the patient any very detailed enquiry into the more remote

causes of the illness and the purposes it served; and, instead, directs her towards a better social adaptation, by advising her to avoid when possible the situations that, as he sees, favour the production of symptoms, getting her into a disciplined way of living, and stepping in with explanation, support and advice whenever fresh difficulties arise. His success in getting rid of individual symptoms at the beginning may be an important factor in establishing the necessary relationship with the patient. Such a line of treatment is not heroic or dramatic, and it demands a great deal of the physician; but it avoids some of the commonest blunders and may be strikingly successful. For this, or indeed any treatment, admission to hospital is not essential; but it will help when there are adverse factors in the patient's situation and, of course, will be essential if there be such symptoms as self-injury, suicidal attempts, pseudo-dementia or gross paralysis. The danger of the patient's picking up new symptoms in hospital should also be weighed. Isolation is usually inadvisable.

Many of the symptoms of hysteria will not wait upon general treatment, but demand energetic intervention. Anorexia, for instance, cannot be allowed to go on to an avoidable inanition, nor a paralysis to the stage of contracture; a mute patient, or one who is deaf or blind or ignorant of his own identity, offers such practical obstacles to almost any kind of treatment that the symptoms must be tackled and disposed of early. For this purpose suggestive measures are valuable and appropriate physical treatment may be called for, *e.g.* supervision during feeding, or even tube-feeding in anorexia nervosa, physiotherapy for paralysis, voice-exercises. Suggestive measures need not take the form of hypnosis; suggestion in the normal waking state has many advantages over hypnosis, though those expert in the latter are sometimes very successful in their treatment. Suggestion, like almost every form of treatment of hysteria, has pitfalls, and its triumphs, like those of every other method, sometimes prove vain, but in the hands of a physician who is at once confident and cautious, this method may result in a satisfactory recovery. If, in using suggestion, such physical devices as faradisation can be avoided, it is better to do so. As a means of demonstrating that the illness is not due to local disease, however, such methods sometimes take their place in a detailed plan of treatment. Motor and sensory symptoms can usually be got rid of if the physician is patient, determined and confident in the use of persuasion and suggestion. Intravenous injection of a barbiturate, such as sodium amytal, may facilitate such treatment, and may help the patient to disclose motives and happenings he had been reluctant or unable to talk about; disclosures of this kind, however, must be received and utilised with caution, and lasting benefit is not to be expected from such catharsis alone.

The choice of occupation, the settlement of any social cause of illness (*e.g.* claims for compensation) and the obtaining of a healthy attitude—neither complaisant, much-enduring nor harsh—on the part of the patient's relatives and friends, are all important factors in treatment. The hysterical reactions to injury call for special mention because of their frequency. Though often of transparent motivation, they are not by any means to be regarded as outright malingering; for the patient's feeling of illness may be sincere, his symptoms distressing, his anxiety typical and his irritability and insomnia symptoms that he would gladly get rid of. But they are none the less psychogenic. It is often assumed that so far as an illness is psychogenic, it must be treated only by psychotherapy. This is false theory. There are few mental disorders in which psychotherapy alone produces such small benefit as in the hysterical conditions due to the compensation or pension situation that may follow an injury. Putting an end to the situation early and the resumption of ordinary activity as soon as any physical injury has been repaired are the most potent measures in the earlier stages. Even if the symptoms have been present a long time, the ending of disputes about claims and the return to ordered routine and regular occupation achieve more than do frequent medical interviews. Psychotherapy is then an adjunct, not an essential feature, of the treatment.

Marriage should never be recommended as treatment for hysteria; the superstition about this has resulted in lamentable troubles, especially for the person the hysteric marries. This is not to say that every hysteric is to be dissuaded from marrying; there are more things than treatment to be considered then. Married hysterics, however, should not be recommended to have—or to adopt—a child. Contrary to popular notions, pregnancy and puerperium more often aggravate than benefit hysteria. Moreover, hysterical women are not usually satisfactory parents, and commonly induce psychopathy in their children.

## ANXIETY STATE

As already stated, the emotional syndrome so called is part of the group of affective disorders, in which depression and manic excitement are also included. It is there described. It would be indefensible to put into a special category all the forms of mental illness in which anxiety is conspicuous, for it can be severe in the most diverse conditions, ranging from delirium tremens to schizophrenia. The outwardly mild form, tending to chronicity and often largely psychogenic, responds well in the less advanced stages to psychotherapy; it is therefore important that its recognition should not be delayed because of a doubt as to physical disease. Yet often the correct diagnosis is overlooked while the patient is being investigated or treated for some local disorder. This arises partly because of the quasi-physical signs of fear which he may show—dizziness, tremor, nausea and vomiting, indigestion, diarrhoea, palpitation, a sense of oppression in the chest, rapid pulse, flushing, sweating, frequent passage of urine, etc. It is still more due to the patient's anxiety turning on his health, especially his physical health, and leading him to ask for more and more medical opinions, radiograms, laboratory investigations, etc., the favourable results of which, however, do not allay his worry. Over-cautious advice as to régime, based on a possibility that there may be some early physical disease, can be harmful to the patient's mental health in that it restricts his normal life, and may constantly recall and reinforce his anxiety. The converse error of mistaking some early symptoms of physical illness for hypochondriacal anxiety is equally to be avoided. Physical investigation of doubtful cases is, in short, indispensable, and should be prompt as well as thorough. When it fails to confirm the presence of a physical disorder the patient should not be treated as though he will still be in danger of the physical illness unless he takes special precautions in diet, exercise, etc. This is well illustrated by such a condition as effort-syndrome, where care taken to avoid any damage to the heart intensifies the illness. The patient should be fully investigated on the psychological side and treated accordingly; this does not mean that he should be treated only by psychotherapy. The discovery of a possible psychological cause for the symptoms does not prove that there is not also a physical cause for them, but it makes it less likely. The converse is also true. For aetiology, diagnosis, prognosis and treatment see section on Affective Disorder (pp. 1645 to 1651).

## OBSESSIONAL DISORDER

**Definition.**—In this condition the characteristic feature is that, along with some mental happening, there is an experience of subjective compulsion and of resistance to it. Commonly the mental happening (which may be a fear, an impulse or a pre-occupation) is recognised, on quiet reflexion, as senseless; nevertheless it persists.

**Ætiology.**—**INTRINSIC.**—The hereditary factor is strong. A third of the parents of obsessional patients, and a fifth of their brothers and sisters, have themselves shown pronounced obsessional traits; the proportion is in each case higher if all forms of mental abnormality be included, since both schizophrenia and affective illnesses occur

some forgotten alarm, and take a queer form, such as a phobia of lavatories or of one-legged men. It is loose usage to give the name "phobia" to every case in which an individual develops fear that is excessive or inexplicable; the essential features of an obsession, already mentioned, should also be present. The term "claustrophobia", for example, is often loosely applied to a fear or dislike of being in an enclosed place, which is not *obsessional*. Fears of dirt or infection are very common phobias: they are symbols of moral, usually sexual, taint, and they lead to much washing, etc.; thus, a patient who has blamed himself for masturbation may be constantly washing his hands, or following a complicated ritual of touching nothing with his bare hands for fear of contamination. Often the rituals and defensive precautions seem grotesque when compared with their ostensible purpose, as in the case of a patient who is perpetually putting himself to the greatest trouble in order to ensure that he never steps on a worm inadvertently. Ludicrous as his behaviour may seem, it is often tragic in the distress, and indeed ruin, it may cause him. Another phobia is that which has fear as its object, i.e. the patient is afraid of any situation in which he may feel fear; some such patients do not leave their homes for years, because they fear they may have "agoraphobia" once they get outside. Obsessional rumination usually takes the form of endless questioning or search. The patient has to ask himself "Why" with pointless insistence about all manner of problems beyond his or anybody's grasp; or he has to keep casting round in his mind after some forgotten name or word which he could easily do without. Religious scruples sometimes fall into this category, as when a penitent is continually running to his confessor with some venial trifle he has come upon in his interminable self-questioning and doubt.

Obsessional patients are in most cases depressed; their illness is a depressing one. Besides this secondary depression, however, there is frequently an association of a more intimate kind, in which depression—or mania—is the essential or the main part of the illness, and the concurrent obsessions seem to be symptoms of this affective disorder. In such cases the obsessional illness is very often cyclical in its course. Anxiety is a common accompaniment of obsessions; in phobias it is most conspicuous. The anxiety is inseparable from the patient's struggle against the subjective compulsion which is so alarming to his feeling of integrity in self and mind, such a shock to his belief that he is a free agent. Schizophrenic symptoms may be in the offing, or actually present, when the obsessional ideas are of the magical kind, e.g. the patient feeling that the effect of his obscene thoughts upon others may be averted by some gesture, or when his rituals are carried to bizarre lengths, e.g. having to save the last drops of his urine because of some recurring doubt. Depersonalisation may occur in the course of an obsessional illness.

**Diagnosis.**—If the essential features, i.e. feeling of subjective compulsion and immediate resistance to this, be kept in view, it is seldom difficult to distinguish between obsessions, on the one hand, and delusions, hallucinations, ideas of reference or self-reproach, feelings of being influenced and schizophrenic stereotypes, etc., on the other. The only difference between obsessions and many schizophrenic phenomena towards which the patient retains insight and which he regards as alien to him, lies in the nature of the compulsion he experiences: in obsessions it is subjective—he feels that it comes from within his own mind, whereas in the schizophrenic phenomena he feels that it comes from without, it is imposed upon him. It is a difference, however, that may be obliterated, i.e. what was once obsessional may become schizophrenic, but this is an uncommon outcome when the obsessional disorder is definite and well-established. In differential diagnosis it must be remembered that obsessions may occur in the course of almost any mental illness in a person of obsessional tendencies, and that the psychological mechanism for the production of obsessions, like that for hysterical symptoms, is present in almost everybody in varying degree. Consequently, an illness is not to be regarded as obsessional unless obsessions are the chief symptoms.

**Course and Prognosis.**—The outlook for recovery is worse if obsessional symptoms have been present since childhood, if they now fill up most of the patient's time, and if he is weakly resigned to his illness. The best outlook is when the obsessional illness comes on suddenly in a person who has not had conspicuous obsessional traits or who has had previous benign attacks. A cyclical course is not uncommon. The situation is ominous when the ritual gets more and more systematised and remote from what previously occasioned it. The development along schizophrenic lines, already mentioned, is more to be feared in such cases and in those with bizarre obsessional thoughts; the great majority of gross obsessionals, however, do not become schizophrenic or anything else than obsessional. About half the cases recover from an attack, which may, however, last for a year or even more. Many people are subject to brief attacks, lasting only a few days, and largely due to fatigue or physical illness reducing their mental health. Intercurrent happenings influence the course of the illness, e.g. some men were free from symptoms during their period of war-service, with its routine and lack of responsibility or need for decision. The content of the obsessions is of little use prognostically. Old age is not in itself an adverse factor, but attacks in childhood suggest a strong constitutional bias and are therefore unfavourable on the whole. Few obsessionals give way to anti-social impulses, e.g. to suicide, homicide, delinquency. It is true that obsessionals who are also depressed may kill themselves, and that obsessionals who are irritable and angry may injure others; but obsessionals rarely yield directly to an impulse they have resisted, or need to have "irresistible impulse" urged in extenuation of a crime. Sexual offences and perversions are rarely obsessional.

**Treatment.**—Patients should be encouraged to continue at their occupation and not to test themselves, or try to overcome their obsession, by repeatedly putting themselves in a situation in which it will occur. So long as their impulses are not likely to get them into trouble, they should be dissuaded from "fighting" them; external restrictions are more helpful than reliance on "will-power". The physician should aim at getting a patient well by putting an end to his anxiety and struggle; if that is not wholly attainable, the patient must be educated to deal with his obsessional tendencies by acknowledging their existence, their psychological origins, and, often, their harmlessness in those very respects in which he thought them most harmful, e.g. obscenity. Frank recognition of obsessional tendencies, which everyone has in some degree, is an important step in learning to control them. In some patients the obsessional attack is so cyclical and almost self-limited that a brief rest and general care are all that are needed. In others, whose affection is chronic, recovery is out of the question, but advice about the management of their lives, varying according to their individual circumstances, helps them greatly. In some such patients frontal leucotomy lessens or removes the distress that formerly accompanied their obsession. Obsessional patients, so prone to rumination and endless questioning, often clamour to be psycho-analysed. There is no evidence that psycho-analysis, however prolonged, benefits them more than methods that are not so exigent of time and money. Obsessional children who may be beset with fears of contamination and religious scruples, usually respond well to changes in their human environment, advised after the physician has enquired into the family and school situation; temporary separation of the obsessional parent or treatment of the latter often proves remarkably beneficial. Discussion of his problems with the child is an important adjunct, just as it would be with an obsessional adult.

## PSYCHOPATHIC PERSONALITY

who do not regard themselves as ill, nor do others think them is abnormal enough to upset or puzzle other people, and

sometimes themselves. In this it is like mental illness, and calls similarly for psychiatric understanding and treatment. But since they are not ill, their behaviour must be attributed to abnormal personality, much as an aberration like alkaptonuria must be attributed to abnormal physical constitution. All abnormality of personality that does not amount to manifest illness may properly be called "psychopathic personality". The term does not connote an evaluation of character, according to how useful such a person is to society, nor is it a prediction about the likelihood of subsequent illness of a particular type; it is a descriptive term. But people of abnormal personality will often come into conflict with organised society and with individuals more normally constituted; they will be on the whole more vulnerable to stresses; their peculiarities, intensified into symptoms of illness or proofs of delinquency, will earn them pity, contempt, dislike, punishment or compulsory treatment. It is therefore common for "psychopathic personality" to be used as a pejorative term, limited to those who will afflict society in some way—the "anti-social psychopath", the "psychopathic tenth", are significant phrases, akin to "psychopathic inferiority" and the still earlier "moral insanity"; or the term is used to denote those who stand in danger of insanity—the "schizoid psychopath", for instance. It is, however, wrong to apply to the concept "psychopathic personality" so shifting and subjective a criterion as social disapproval, nor can mental illness be assumed to be a certain outcome in even pronounced aberrations of personality. Among mystics and poets, men of action, scholars and scientists are some who have properly been classified as of "psychopathic personality", their abnormality consisting nevertheless in unusually high, rare and valuable if peculiar qualities, rather than in a blemish or handicap. St. Teresa, Joan of Arc, T. E. Lawrence, Cavendish, Cellini, Tolstoy, Mozart, Michelangelo—any hurried list of famous people that have been cited as examples of psychopathic personality, testifies to this. Apart therefore from any judgement about the good or harm they do to society, people are said to have a psychopathic personality if they fall outside the wide range agreed upon as normal—not quite the same thing as healthy—yet are not ill. Society being ordered as it is, the majority of such abnormal people will at some time come into conflict with it or fail to meet its demands and their conduct will often rightly be called anti-social. The anti-social group of persons with psychopathic personality is large; its size will vary according to the culture in which they live and the allowances or opportunities it makes for them. This is obviously true if their adjustment as adults to the demands of the community is the measure of their "anti-social" trends; it is true also of their development and the way in which social influences may be such as to foster their smooth participation in a very diverse pattern of human relationships, or may mar them, giving neither free play nor direction to their peculiarities. Success in preventing many of these abnormal people from becoming a nuisance or a danger is, therefore, a test of the educational methods, the pliancy and the psychiatric hygiene of a community. This is not to ignore the hereditary and narrowly individual factors which determine psychic constitution, but to stress the social causes of later social failure, should it occur; such failure, however, need not be regarded as inevitable in people of psychopathic personality.

Classification of psychopathic personality can be (1) arbitrary, (2) psychological or (3) psychiatric. The first picks out what seem serviceable characteristics that occur often and conspicuously; thus, one well-sponsored list is made up of the excitable, the unstable, the impulsive, the eccentric and perverse, the quarrelsome, the anti-social, and the liars and swindlers, and makes further reference to aesthetes, scatterbrains, enthusiasts and fanatics. The second, which is the ideal method, is based on the varieties of normal personality. Unfortunately, the types, trait-clusters and other classificatory groups so far proposed do too little justice to the complexity and range of human personality to be satisfactory or lasting. The third, or psychiatric, classification, is likewise provisional but it has the advantage of grouping

these non-morbid abnormalities in the same categories as the severe, morbid ones (with which there is reason to believe them genetically connected). To do this begs some fundamental questions, but it is for the present useful to recognise schizoid, affective, paranoid, obsessional, hysteric and perhaps epileptic varieties of psychopathic personality. This list is open to the objections that must be made to any attempt at stating types of personality, and it is wrong to suppose that any of the varieties mentioned must always precede, or indicate proneness to, the illness from which its epithet is derived. Nevertheless, they give the psychiatrist a familiar frame of reference and they leave room for manifold combinations of traits and attitudes within each class, so that the individual drug-addict, the sexual pervert, the hypochondriac and the fanatic can be included. If this psychiatric classification were to be judged by as rigorous a standard as the psychological, it could not stand; it will no doubt eventually give way before a surer psychology of personality and a surer psychopathology, as indeed it would have to now if the psycho-analytical conception of the structure of normal and morbid personality were accepted as final. For the time being, it is convenient to use these derivative terms, such as schizoid, and to give them no more weight than the bare labelling of personality deserves. Understanding a psychopathic person's motives and conduct, of course, requires full consideration of his development, circumstances and traits and goes beyond their classification for clinical purposes.

Besides the hereditary and social causes of psychopathic personality, anomalies of cerebral structure may contribute to the condition. But in childhood and even in maturity damage to the brain, by infection, poisoning, malnutrition or trauma, can lead to changes in personality, such as occur after encephalitis, carbon monoxide intoxication, pellagra, operations and accidental violence to the brain. They do not conform to a single pattern, and may be complicated by intellectual impairment. They depend to some extent on the part of the brain affected; in perhaps the most striking group—encephalopaths whose emotional control is much reduced so that they easily become violent when they cannot get their own way—the hypothalamus and other structures in the rhinencephalon are suspect. Electro-encephalographic data have recently been added to the clinical, psychological and experimental evidence for this. Some writers believe that most of those with psychopathic personality characterised by violent outbursts have an innate or acquired cerebral abnormality, and even, though on inconclusive grounds, that there is a kinship between the aggressive psychopath and the epileptic. It would, however, be a mistake to attribute psychopathic personality, even when marked by excitability and impulsive acts of violence, mainly to anomalies of cerebral constitution; emotional deprivation or insecurity during childhood, parental mismanagement, and in adult life severe frustration and adversity constitute psychological causes which are often in evidence.

Any description of forms of psychopathic personality must be lengthy, as must also any consideration of their psychopathology and treatment. Crime, juvenile misbehaviour, habitual or sporadic drug-taking, peculiarities of sexual desire and practice, incapacity for certain occupations and public duties (e.g. school teaching, military service), the temperamental concomitants of inferior intelligence and, at the other extreme, some of the characteristics of genius; these are intimately linked with the problem of psychopathic personality, and their exposition would demand a fuller treatment than space allows.

## MENTAL DEFICIENCY

As already stated (p. 1626), there is nothing in principle to separate these from other forms of mental anomaly save that they occur at an earlier stage of life. Like mental disorder, they shade into normality; no man can say where stupidity ends

and feeble-mindedness begins. Again, as with mental disorder, the same clinical picture may be due to a variety of causes ranging from heredity to trauma. They are, moreover, delimited rather by social than by other criteria, and they are not definitely associated with any constant pathological findings, except in the numerically limited group of special clinical types. In that they are capable of only limited improvement when well established, and that the intellectual functions are more obviously damaged than any others, their similarity to cerebral impairment in adult life is easily seen. They are not by any means cases of purely intellectual defect; they represent, it is true, one extreme on the scale which has people of great intellectual ability at its other end; but they are also examples of a general impairment of mind, affecting the emotional and conative functions, and often associated with a more general impairment of the whole organism, which may be seen in its physical structure. Since the milder forms are indistinguishable (except on an arbitrary reckoning) from what may be termed normal stupidity, it is difficult to use rigorously the official definition of mental defect, as a condition of arrested or incomplete development of mind existing before the age of 18 years, whether arising from inherent causes or induced by disease or injury; but the description is serviceable. It should be recognised that, just as "psychosis" differs from "neurosis" only in a rough social sense, turning on the need for special care, and "neurosis" from "normality" only in respect of the limitations the former imposes on one's daily life as a social organism, so does the distinction between normality and feeble-mindedness, and between gross or certifiable deficiency and the lesser forms, turn on the social adaptation of the person in question. To complete the points of similarity there is recognised a "moral defectiveness", which has its parallel in some kinds of "psychopathic personality". The effects of encephalitis lethargica, parenchymatous syphilis and thyroid deficiency upon the mental state and development at different ages, or the varying results of amaurotic familial idiocy in the infantile and the delayed juvenile form, illustrate how important is the stage of growth or maturity at which damage is done.

**Ætiology.**—The customary division is into primary (hereditary) and secondary forms, but a less dogmatic distinction is between those who represent the lower extreme of normal variation (the "subcultural" group) and those in whom a gross structural pathology is discoverable. The former group is a large one, making up approximately three-quarters of all cases of mental defect. This is an estimate arrived at by independent workers, but it may have to be changed as we acquire better methods of determination and fuller knowledge of the subtle interplay between environment and heredity. The grosser the deficiency the less important the hereditary factor, except in some rare well-defined anomalies, such as amaurotic idiocy. Familial concentration of a given form of defect is specific for each clinical type. A combination of several genetic factors is probably responsible for all but the special types: the mode of transmission of amaurotic familial idiocy and of phenylketonuria is recessive; that of epiloia dominant.

The environmental causes are prenatal, congenital or infantile; they include birth injury to the brain, meningo-encephalitis, hydrocephalus, cerebral syphilis. Various poisons and deficiencies may be responsible, as in the well-known instance of cretinism, as well as certain malformations of the cerebral tissue, e.g. microgyria and porencephaly, and of the cranium, e.g. oxycephaly. The influence of maternal rubella and other exanthemata, and of Rh incompatibility upon the fœtus have lately been studied in this connection. Sensory defects, as in a deaf-mute, may greatly impair mental development. It is possible that some cases of schizophrenia beginning in the first few years of life are indistinguishable from mental defect and are diagnosed as such.

**Pathology.**—In many cases there are no significant findings; this is particularly the case with high grade defect. It is probably impossible from the histological appearances to infer the extent of hereditary or exogenous causation. Develop-

mental anomalies, such as general hypoplasia and microgyria may, however, be mingled with evidences of a past lesion, as in porencephaly or hemiatrophy, or with signs of a disease actually present, as in amaurotic idiocy, cerebral lues and tuberosc sclerosis. Localised lipoid deposits in the brain are found in amaurotic idiocy, Schuller-Christian's disease, gargoylism and Niemann-Pick's disease.

**Symptoms.**—The usual classification is into idiots (who are too defective to be able to guard themselves against common physical dangers like falling into the fire), and imbeciles and feeble-minded persons (who need to be looked after because of their incapacity to manage their affairs or to profit by instruction). Imbeciles cannot earn their living; the feeble-minded cannot get on in an ordinary school, but may learn a good deal in a special school and be able to earn a living. The criterion is in each case mainly a social one; the same is true of "moral defect", *i.e.* mental defect coupled with strong vicious or criminal propensities. Although these terms are defined in an Act of Parliament, they are vague and of administrative rather than medical use. An attempt has been made to render them more precise by psychometric means: the customary tests for mental age (usually the Stanford-Binet) are

applied, and if the subject's intelligence-quotient  $\left( \frac{\text{mental age}}{\text{actual age}} \times \frac{100}{1} \right)$  be less than 20,

he is called an idiot; if it be between 20 and 50, an imbecile; if between 50 and 70, feeble-minded. It must, however, be recognised that though mental defect is mainly a matter of intellectual capacity, it is not solely this, and that intelligence tests, however valuable and trustworthy, cannot give a complete indication of the degree of mental defect. Even the intellectual defect may be uneven, showing much more in some tasks than in others, and it would be a gross error to suppose that a mentally defective person with a mental age of, say, 9½ years is mentally in the same state as a normal child aged 9½ years.

The physical symptoms are chiefly due to lesions of the central nervous system: birth trauma may have led to paralysis, spasticity, athetosis; or there may be evidence of an inflammatory condition of the brain and its membranes, as from syphilis. The whole clinical picture may be greatly coloured by the motor disturbance, *e.g.* continual rocking and twisting movements, grimaces and abnormal posture. The special senses may be affected, as the result of an independent anomaly, *e.g.* coloboma, misshapen ears; or from a common cause, *e.g.* interstitial keratitis, the retinal changes of amaurotic idiocy. It is dubious whether the "stigmata of degeneration", such as a "Gothic" palate or a Darwinian tubercle, occur any more frequently among defectives than in the rest of the population: at all events, there is none that can be used diagnostically, except in the case of mongoloid idiocy. There are, however, some correlations between somatic anomalies and mental defect. Thus, there are more physical defects among these people than in the average population, and this becomes more evident as one looks lower in the scale of mental defect, in which skeletal and cardiovascular anomalies may fairly often be found, sometimes, but not always, due to thyroid or pituitary disorders. The mongoloid variety is described below.

The mental symptoms are lack of intelligence and of the normal exercise and control of primitive tendencies. This may be extreme, as in idiots, who cannot be taught to feed themselves and keep clean or who can only just recognise their companions and make their elementary needs known—they are, indeed, much less intelligent than an animal. Imbeciles are usually incapable of learning and remembering any but very simple matters. They may, however, be able to do automatically what they cannot understand or put to independent purpose: thus, "idiots savants" are especially clever at doing mental arithmetic, recalling dates and other such operations. What imbeciles manage to learn they cannot utilise in any but the most familiar circumstances. Abstract concepts are too hard for them, and their judgement is as poor as their grasp or awareness of what is relevant in any situation. Though in many

ways suggestible and accessible to flattery, they may be obstinate and egotistical, and readily fall into anti-social courses, e.g. prostitution, vagrancy, crime. Crude sexual offences or murder may be committed as lightly as some minor deception. The personality of imbeciles varies widely: some are docile and kindly, others rough or deceitful and vindictive. It depends much on their upbringing. It has been found that in satisfactory conditions only about 8 per cent. of defectives show anti-social or troublesome behaviour. But though the deviations of personality may not lead to delinquency, it is common to find in mentally deficient persons defects of temperament and character, as well as of intelligence, which are reflected in social inefficiency. This is most important in the feeble-minded, who have intelligence enough to learn an occupation; whether they can earn their living by it will depend on their character and the way they have been brought up.

Many persons who are high-grade defectives, when measured by formal tests, are not taken to be such because of their social adaptability, their fluency and capacity for keeping their heads above water as long as economic and other stresses are light. There are instances of people classed as mentally defective during childhood, because of their backwardness in school and their low score in tests, who later in life amass money by their own efforts, or even hold responsible positions. A majority of high-grade defectives, however, live dependent and often troublesome lives; at most they do simple repetitive work. Many of them are unstable creatures, whose psychopathic personality may be sufficiently anti-social for the term "moral deficiency" to apply to them. Hysterical trends may show themselves in crude phenomena, e.g. convulsions, counterfeit insanity or fantastic lying; and religious and artistic pretensions may take in gullible followers and even lead to the founding of ephemeral movements.

Defectives are prone to disturbances of mood, sometimes arising out of awareness of their inferiority and its social consequences. Sudden outbursts of excitement may show similarity to manic or catatonic hyperkinetic states; they may be accompanied by a paranoid hallucinosis, mainly auditory, which clears up with startling rapidity in a day or two. In respect of these psychotic episodes, defectives are like epileptics and juvenile encephalitics, in whom a cerebral impairment has likewise occurred before the attainment of maturity. Some of the morbid phenomena, especially in idiots, are very similar to the disorders of motility seen in schizophrenics, because, it may be assumed, the same bodily mechanisms are implicated.

The *mongoloid* type of defect is characterised by striking physical features. Probably the outcome of intra-uterine conditions, it is most frequent in last-born children in a large family, or in children born of elderly mothers; parental syphilis may occasionally be the cause. In many cases the brain-stem and cerebellum have been disproportionately small, and other signs of maldevelopment have been reported. Cerebral metabolism is abnormally low. It is likely that hereditary factors of an irregularly dominant nature also play a part. The condition is usually present from birth; physical growth is slow, and has stopped by the time the child is 15. Defective growth of the skull, leading especially to abnormalities of the base and the orbit, are responsible for the peculiarities of cranial shape. The pituitary gland has been reported as showing an increase in eosinophil cells and deficiency of basophil cells. The appearance of these usually happy idiots and imbeciles is rather suggestive of a Mongol or of a fœtus. The skull is small and round, and the junction of occiput and back of neck flat; an epicanthic fold across each inner canthus, narrow tilted eye-slits and lids without lashes, red cheeks, fissured and often protruding tongue, stubby depressed nose with nostrils looking forward, irregular late-appearing teeth, coarse hair on the scalp, small facial bones and occasional neurological anomalies, such as nystagmus, make the head of every mongoloid a disagreeable but ready index to his disorder. That the disorder is a general one the rest of his body testifies; his limbs are lax and over-mobile at the joints; he has broad, clumsy feet and hands (with short fingers, a special pattern between the base of the third and fourth fingers, and a crease

depending as they do to some degree on the subject's attitude and situation at the time, about which the group-tester will know little or nothing, and they cannot be trusted when a low score has been obtained. In all instances where a decision must be taken that depends partly on the results of the test, any puzzling or unduly low score on a group test should be reinforced by an individual test, such as the Binet or Bellevue. It must, however, be admitted that the inexpert administration of individual tests can yield as rich a crop of wrong conclusions as can the uncritically accepted group test. The truth is that "no mental test score should ever be accepted at its face value, nor trusted in the same way as physical measurements are trusted. . . . No one ought to use tests who is not willing to familiarise himself with the underlying principles which must be understood if tests are to be applied and interpreted properly, and with the literature which bears on the particular tests that he employs. In skilled hands, testing provides a far surer and more accurate tool for the assessment of abilities than do subjective impressions or the ordinary examination paper. But human nature is far too complex to be measured in the simple and direct ways in which physical quantities can be measured, and the over-enthusiastic but unskilled tester is only too likely to make serious mistakes."

**Treatment.—PROPHYLACTIC.**—Eugenic measures are desirable for the rare hereditary conditions, like amaurotic idiocy, and in the case of those imbeciles and feeble-minded in whom genetic rather than environmental causes have been responsible for their maldevelopment and who are capable and desirous of procreating; idiots do not procreate. Voluntary sterilisation for eugenic reasons has been recommended by a Departmental Committee, but has not yet been explicitly sanctioned by law. Birth control, therefore, is the eugenic measure to be advised in cases in which defectives seem likely to transmit their defect; unfortunately few such defectives can be relied on to observe contraceptive precautions effectively. Segregation may indirectly serve the same end. Well-managed partition and treatment of parental syphilis are the only other practicable ways of forestalling defect.

**Educational and social.**—Much improvement may be attained by the training of defectives; it is work for experts. Many high-grade defectives who would otherwise spend their lives in an institution can be prepared by suitable graduated work under sheltered conditions for an independent life in the general community. Where there are special disabilities, *e.g.* of the senses, or of such capacities as reading and writing, attention to these may lift the child out of the class of mental defectives altogether; so may education designed to promote emotional stability and self-confidence. Whether a child lives at home or in a colony or institution will depend not only on the degree of his intellectual and social deficiency, but also on the adequacy of his home circumstances. There are many kinds of provision for the care of some of the 300,000 defectives in England and Wales, ranging from special schools and statutory supervision to mental hospitals; an eighth are in certified institutions, and a thirtieth more in public assistance institutions. Well-run colonies providing adequate psychological and occupational as well as psychotherapeutic and other clinical services succeed in socialising many defectives hitherto vicious or violent, who can then go out and live usefully in the community or in hostels. Some, however, prove intractable, especially those who have epileptic fits.

**Physical.**—The bodily disturbances, *e.g.* contractures and paresis, call for orthopaedic treatment, which sometimes benefits the mental state. The treatment of the forms due to thyroid deficiency or syphilis is described elsewhere.

Histoplasmosis	page	i
Toxoplasmosis		v

## APPENDIX

### HISTOPLASMOSIS

**Definition.**—An acute, subacute or chronic infection of man and certain animals by the fungus *Histoplasma capsulatum*, giving rise to three main clinical types of disease: (i) the disseminated form, where the parasites invade the reticulo-endothelial cells in many parts of the body; (ii) the primary pulmonary form confined to the lungs and adjacent lymph-nodes; (iii) a localised infection of the skin or the mucous membranes of the mouth, tongue or pharynx.

**Ætiology.**—The fungus exists in two forms: (i) a mycelial phase which is found when it is existing as a saprophyte or if it is cultured at a temperature of 22° C.; (ii) a yeast-like phase which occurs when it is living as a parasite or if it is grown on enriched media at 37° C. Infection from natural sources is probably due to the mycelial phase, but it is the yeast-like phase that is parasitic and invades the tissue cells; change from one form to the other readily occurs.

The fungus has been isolated from the soil in many areas and some twenty species of animal have been found to harbour the parasite, the bulk of natural infections being found in dogs, cats and rats; it has also been found in a high proportion of skunks and opossums, but only small numbers of these animals have been examined. Birds have not been found infected with *Histoplasma*, and seem to be highly resistant to it, though the fungus can be found in profusion in their droppings and in the litter of poultry houses. A number of small epidemics have occurred on farms in the United States, and amongst builders working in lofts where birds roost, caused probably by inhalation of infected dust. The adoption of the deep-litter method of poultry farming in this country suggests the possibility of similar outbreaks arising, particularly in the more humid western counties. Both sexes are susceptible at all ages, the highest incidence being either during the first year of life or in the later adult years. Amongst adults, males are infected seven times as frequently as females.

The chief portal of entry is thought to be the respiratory tract, but the disseminated form may originate in some part of the gastro-intestinal canal. Primary skin lesions also occur but they are uncommon. Special precautions seem necessary in laboratories, as already 41 cases of infection, with clinical illness, have been reported amongst laboratory workers who had been handling *H. capsulatum*. The incubation period is not known with certainty but is thought usually to be from 4 to 6 weeks, with a range of from 2 weeks to 3 months. *H. capsulatum* has a world-wide distribution although clinical cases occur somewhat sporadically outside North America. In Great Britain at least 15 cases have been diagnosed with certainty, but it is thought that in the majority the infection was acquired elsewhere. The principal endemic centre is in the United States of America, where the greatest incidence is found in an area extending from the Great Lakes to the Gulf of Mexico, in the valleys of Ohio, Missouri, Arkansas and Mississippi rivers.

**Pathology.**—The fungus invades and multiplies within the reticulo-endothelial cells and in the disseminated form it may be found throughout the body or confined to a single organ; the suprarenal glands often being the principal or only organ involved. In acute disseminated infections with a fatal termination, intra-cellular organisms may usually be found post mortem in stained sections of tissue from the lung, liver, spleen and suprarenal glands. The gastro-intestinal tract is often affected, and the bone marrow almost invariably. The organism produces greyish-white nodules, usually multiple, varying in diameter from 2 to 3 mm. up to several centimetres. Extensive areas of necrosis may be found surrounded by granulomatous

tissue. Superficial or deep ulcers may be seen in the small or large intestine and nodules have been found in the submucosa and deeper layers of the intestinal wall. Caseation of the suprarenal glands may cause almost total destruction of glandular tissue, and a recent review of 103 fatal cases of histoplasmosis revealed that 35 per cent. were found post mortem to have some damage to suprarenal glands. Infections commencing in the mouth, pharynx or larynx show localised necrotic ulcerations and enlargement of the regional lymph nodes.

In the benign pulmonary infections multiple, small, discrete, fibrotic nodules may be found in any part of the lungs, and early enlargement of the tracheo-bronchial and hilar lymphatic glands is usual. The central portions of the nodules become caseous and later calcify: these residual lesions are often seen in a routine radiograph taken months or years after the infection occurred. When the lung is involved in the disseminated form of the disease there is usually an extensive, bilateral, interstitial pneumonitis in the early stage of the illness with diffuse or localised areas of consolidation. At times abscess formation occurs, which may be followed by cavitation. Where healing takes place, fibrosis with contraction often causes deformity of a section or lobe, and a clinical diagnosis of chronic tuberculosis or bronchiectasis is not an uncommon error; where it occurs near the lung roots it may be mistaken for a bronchogenic carcinoma. Occasionally the infection is confined to the mediastinal lymph nodes and a picture almost indistinguishable from Boeck's sarcoid or lymphoma is presented.

**Clinical Features.**—(i) *Disseminated histoplasmosis.*—This may be an acute and rapidly fatal illness and this form is most common in infants, in the aged, or in those debilitated by tuberculosis or malignant disease. More commonly it runs a sub-acute course, the illness extending over many months, with a fatal termination in most instances, although arrest of the disease and ultimate recovery have been recorded a number of times.

There is no characteristic clinical picture. Common early features are debility, loss of weight, low-grade fever, sweating, joint and muscle pains, abdominal discomfort and diarrhoea. Leucopenia and progressive anaemia are almost invariable and enlargement of the liver and spleen are usually found. Involvement of the suprarenal glands may destroy so much glandular tissue that Addison's disease results, and histoplasmosis should always be excluded when such a diagnosis is made. If the infection spreads to the lung it will usually give rise to a pneumonitis, with an abrupt onset accompanied by fever around 103° to 104° F., but seldom any clinical features to distinguish it from a viral pneumonia. Symptoms may be limited to occasional chest pain and a dry unproductive cough. The physical signs are seldom of any diagnostic value. By contrast a radiograph shows an extensive bilateral interstitial pneumonitis, miliary or patchy, together with enlarged hilar lymph nodes. The acute stage lasts for 7 to 10 days, followed by gradual subsidence. The radiographic signs, however, do not reach their maximum for 2 weeks; after 6 weeks a fine nodular fibrosis may be seen, and after 3 months nothing abnormal may be detected. More often though, when recovery takes place, contraction follows the fibrosis with marked deformity of the affected lung section.

(ii) *Primary pulmonary histoplasmosis.*—This form is very often asymptomatic; it may cause mild catarrhal symptoms and malaise, and suggest influenza or bronchitis. Spontaneous recovery is the rule and the disease is seldom recognised before this has taken place. It may be months or years before the residual lesions are seen in a radiograph, as the examination is nearly always made either as a routine or for some other condition.

**Laboratory Findings.**—The fungus may usually be found in the cytoplasm of the reticulo-endothelial cells and in the macrophage cells, in the form of round or oval yeast-like bodies varying from 2 $\mu$  to 4 $\mu$  in diameter. Smears stained by Giemsa's method show chromatin irregularly condensed within a refractile capsule. The

organism is found most easily in smears obtained by sternal or splenic puncture but may also be seen in smears from the lesions, where these are accessible, and at times in the cytoplasm of the mononuclear blood cells. Very occasionally in heavy infections a direct sputum smear will show the organism.

**Culture.**—If the infection is scanty, culture will be necessary and this is the method for definitive diagnosis. Cultures should be made on enriched blood agar to which small quantities of penicillin and streptomycin have been added. Infected material such as blood, bone marrow or sputum should be rubbed over the culture medium, the plates then being closely sealed with "cellophane" tape. It is essential to incubate some of the plates at room temperature as at 37° C. only yeast-like bodies are produced. At room temperature an abundant aerial mycelium is formed consisting of septate hyphae with numerous microconidia attached to their sides or growing on short lateral branches. In addition there are the rounded tuberculate chlamydospores which are characteristic of *H. capsulatum* and their presence makes diagnosis conclusive. The material used for culture must be fresh and the cultures should be observed for 6 to 8 weeks before they may be considered negative.

**Histoplasmin Skin Reaction.**—The histoplasmin skin reaction develops within a few weeks of infection. 0.1 ml. of a 1:1000 dilution of standardised histoplasmin is injected intracutaneously. The reaction is read after 48 to 72 hours in the same way as for the tuberculin test. A positive reaction is found not only during the clinical stage of the disease but in many healthy persons living in endemic areas. As such reactors have an unusually high incidence of pulmonary calcification, it seems probable that a past infection with *Histoplasma* has healed spontaneously without causing any recognisable illness.

**Complement Fixation Test.**—In acute infections, complement fixing bodies appear in the blood towards the end of the third week of the illness and increase during its course, gradually diminishing as recovery sets in. In chronic pulmonary infections they may persist at a high level for many years. The complement fixation test is a valuable aid to diagnosis and should be employed whenever infection by *H. capsulatum* is suspected. The test may become negative in the terminal phase of the disseminated form of the disease but the fungus can then usually be identified readily by blood or bone marrow culture; or by the examination of tissues obtained after biopsy has been performed. The antibodies produced cross with the antigens of other fungi, particularly *coccidioides immitis* and *blastomyces dermatitidis*. These cross reactions do not, however, invalidate the complement fixation test as the titres of the homologous antigen are significantly higher.

When biopsy is possible, sections of enlarged lymph nodes or of tissues from superficial lesions may show endothelial cells packed with *H. capsulatum*. Caution is necessary, however, when considering biopsy, since two recent case histories have revealed that shortly after a biopsy was performed, each patient having been previously in good health, generalised symptoms typical of the disseminated form of histoplasmosis arose, followed by death a few months later. The diagnosis was confirmed post mortem and it appears possible that the organism was disseminated into the blood-stream when the biopsy was performed.

**Prognosis.**—In the past histoplasmosis was often considered to be an almost invariably fatal disease. More recent knowledge indicates that the mortality is probably extremely low, since it is considered reasonable to assume that a positive histoplasmin skin test indicates past invasion of the tissues of some part of the body by the fungus, and such positive reactions have been obtained from several millions of persons in the United States. Such persons often have scattered calcified areas in the lungs such as are found after histoplasmosis. It is thought, therefore, that the majority of infections are overcome without any noticeable disturbance of health, or the disease passes unrecognised, as the illness is of short duration and spontaneous recovery ensues.

Where the diagnosis is made during the clinical course of the disease, it may be

said that in primary pulmonary histoplasmosis, recovery nearly always occurs spontaneously and the prognosis is excellent. Localised infections are more serious, and run a much more prolonged course. They usually progress by localised extension, and unless the disease is arrested they tend to be ultimately fatal. There are, however, a number of records where the disease has continued for many years without any serious disturbance of health to the persons affected.

More than one-quarter of the fatal illnesses occur in infants under 1 year of age. In these, the disease is nearly always in the disseminated form, and up to the present time it has been found that over two-thirds of all cases of disseminated histoplasmosis have a fatal termination.

**Treatment.**—It is fortunate that the great majority of cases recover unaided, since despite favourable initial reports on a number of new compounds, there is not yet sufficient evidence to consider any of them curative.

Most of the established antibiotics and sulphonamides have been tried and they have all been reported to be ineffective, although recent laboratory trials have shown that several sulphonamide compounds do have a pronounced action on *Histoplasma* and are capable of overcoming infections in mice previously inoculated with lethal doses of *H. capsulatum*. Sulphanilyl thiourea is by far the most active of the many compounds tested, possibly because, unlike most of the other sulphonamides, it is only partially inactivated by *p*-aminobenzoic acid. The yeast phase of the fungus is far more sensitive to the drug than is the mycelial phase, and this may explain its efficacy in histoplasmosis in mice, which is usually a very acute and rapidly fatal infection. In the more chronic infections, common in humans, the mycelial phase of the fungus may predominate, making its eradication much more difficult. Further clinical trials of sulphonamides seem necessary.

The use of cortisone and related compounds should be avoided in histoplasmosis, as it has been found that the initial improvement that often occurs following their administration is temporary, and rapid extension of the disease often follows. When the suprarenal glands have sustained such severe damage that Addisonian crises occur, cortisone will be necessary to tide over the crisis, and to prevent their recurrence small maintenance doses together possibly with DOCA should be given.

Ethyl vanillate received favourable reports when first used, but later trials failed to confirm its value. Stilbamidine, and more recently 2-hydroxy-stilbamidine have been used, and they have appeared to have a favourable influence upon the course of the disease, although the response to their administration is somewhat uncertain.

Two drugs still undergoing laboratory trials have given encouraging results, combining powerful anti-fungal properties with low toxicity for many different species of animal. One, nystatin (fungicidin), is an antibiotic which has been marketed under the trade name of Mycostatin. In laboratory animals it has proved to be highly effective in all forms of infection, whether fulminating, moderately acute or chronic, and the therapeutic doses have not been toxic. In contradistinction to sulphanilyl thiourea, nystatin is more active against the mycelial phase of *H. capsulatum*. If the preliminary reports on these two drugs are substantiated, treatment with a combination of the two may prove to be highly effective.

The other drug, MRD-112 ( $\beta$ -diethylaminoethyl fencholate) also has marked anti-fungal properties combined with a low toxicity. In human infections it has been given by intravenous injection, commencing with a dose of 50 mg. daily, later increased to 150 mg. daily, the duration of treatment being 24 to 28 days. The higher dose may cause drowsiness at first, but clinical improvement has been apparent soon after the commencement of treatment, although radiographic studies have shown very little change in the lungs throughout this period. It should, however, be remembered that in cases with an acute pneumonitis, due to histoplasmosis, the radiographic signs in the lung do not usually reach their maximum for 2 to 3 weeks after the onset, although subsidence of the infection often commences after 7 to 10 days.

## TOXOPLASMOSIS

**Definition.**—An uncommon disease of man and animals, of world-wide distribution, caused by a small protozoon, *Toxoplasma gondii*, which may be transmitted to the foetus *in utero* by an infected mother or acquired by some means as yet unknown in childhood or in adult life. The majority of infections probably pass unnoticed but the parasite may give rise to a wide variety of symptoms and signs, of differing severity and variable duration, depending partly upon the age of the person when infected, which tend to be so grouped that four main clinical types of illness may be recognised.

1. **CONGENITAL.**—This form is characterised by encephalomyelitis, cerebral calcification, hydrocephalus and choroidoretinitis; with symptoms either apparent at birth, or appearing soon afterwards.

2. **ACQUIRED.**—

- (i) *Cerebrospinal*—most frequent in children in whom the most typical manifestations are those of an acute meningoencephalitis;
- (ii) *Lymphatic*—characterised by the enlargement of one or more groups of lymphatic glands, with at times fever of several weeks' duration and marked constitutional disturbance;
- (iii) *Exanthematous*—the form most frequently found in adults, presenting as an acute febrile illness with a widespread maculo-papular rash, a diffuse interstitial pneumonitis, myocarditis and at times meningoencephalitis;
- (iv) *Latent*—where infection by *T. gondii* gives rise to no symptoms or signs of the disease, and diagnosis can only be made by means of laboratory tests. Latent infections are found only in adults, and are probably always acquired after the age of childhood.

**Ætiology.**—The causal organism was first discovered in 1908, in a small North African rodent, the gundi (*ctenodactylus gundi*), and it was named *Toxoplasma gondii* Nicolle and Manceaux. It was thought to be a protozoon and was classified as one of the sporozoa, but there is still much doubt about its true position. Although many species have since been described, *T. gondii* is considered the only species occurring in man and animals, all other forms described being considered strains of a single species, since both morphologically and immunologically they all appear to be identical.

*T. gondii* is an intracellular parasite found usually in the endothelial cells, the mononuclear leucocytes or the tissue cells. Free living forms may also be found in the tissue fluids of the host. In this free extracellular form, the parasite is a slender crescent-shaped organism, with one end rounded and the other pointed, measuring from  $4\mu$  to  $6\mu$  in length, its breadth being around  $2\mu$ . Intracellular forms often lose the crescent shape, becoming pear-shaped, oval or rounded when they may readily be confused with *Leishmania*. In dry films stained by Wright's or Giemsa's methods, the cytoplasm is blue, the granular nucleus, which is single and fills about one-quarter of the cell, stains a reddish purple and will be seen near the rounded extremity, whilst towards the pointed end there is a small deeply staining red granule, the paranuclear body. The parasite multiplies by longitudinal fission within the endothelial and tissue cells of its host. With virulent strains these cells rupture early, releasing the parasites which then invade fresh cells, thus enabling the parasite to multiply extremely rapidly; though, in the light of present knowledge, with doubtful benefit to itself, since it may result in an overwhelming and rapidly fatal infection of its host. With less virulent strains the cells often remain intact, allowing reproduction to continue until they become greatly distended by 80 or more parasites;

their nuclei are then extruded, and the hypertrophied, cyst-like structures that remain, packed with parasites, are known as pseudocysts. Within them the parasites seem to be in a resting or inactive stage, causing little tissue damage or cellular reaction, the cyst wall probably affording protection from any circulating antibodies, thereby enabling a chronic infection to become established.

*T. gondii* can be cultivated in the laboratory if living tissue cells are used. It propagates most readily on the chorio-allantoic membrane of the developing chick embryo at 35° to 37° C. if protected from bacterial contamination and dehydration. The embryo usually dies between the seventh and tenth days.

**Epidemiology.**—*Toxoplasma gondii* has been found in many species of mammals and birds, and also in certain reptiles. The first authenticated report of human infection was made in 1923, since when human infections have been recorded in many European countries, including Great Britain; in the Middle East; Ceylon; North, Central and South America; Australia and Hawaii. The incidence of toxoplasmosis in man is not known yet, but subclinical infections are probably much more frequent than it is generally realised. Recent surveys using serological tests have shown that positive reactions, suggesting a past infection, may be given by from 10 to 50 per cent. of the adult population in many areas. Such figures should, however, be treated with caution, since doubt has been cast on the validity of some of the tests used, it having been found that they are not specific for *T. gondii*.

Very little is known about the transmission of the parasite to humans or of the source whence it originates, though it is thought to be conveyed from animal reservoirs by some means still awaiting discovery. Rodents and dogs in particular are thought to be a possible source of infection.

Neonatal infections appear to be conveyed transplacentally to the foetus from an infected mother, who almost invariably remains free from any symptoms of the disease herself. If the infection is acquired early in pregnancy by the mother, abortion will probably result, or if the pregnancy continues the foetus will be so extensively damaged that it will be stillborn. Infection late in pregnancy may result in the infant being free from any signs of the disease at birth, and several weeks or even 2 or 3 months may elapse before signs and symptoms appear. Later offspring from such mothers, with one possible exception, have never yet been born with toxoplasmosis. It seems probable that if the mother became infected during the puerperium the disease could be transmitted to the infant if it was breast-fed, as lactating laboratory mice have conveyed the parasite to their offspring in the milk.

Laboratory workers handling *Toxoplasma* have several times acquired very severe or fatal infections, though by what means remains unknown.

Direct case to case infection seems improbable, since laboratory animals have hardly ever been known to infect their cage-mates even in experimental conditions planned to achieve it. In the adult form of the disease with a diffuse pneumonitis, the parasites are often plentiful in the secretions in the small bronchioles, and in such cases droplet infection would seem a possibility.

Nearly all warm-blooded species of animals can be infected experimentally and the parasite has been transmitted in the laboratory :

- (i) by feeding to animals, either tissues containing it or food contaminated with faeces in which it is present;
- (ii) by inoculation by almost any of the usual routes, intranasal, intravenous, intraperitoneal, intracerebral or subcutaneous;
- (iii) by direct penetration of closely shaved skin by the parasite;
- (iv) by penetration of the mucous membrane of the vagina and the conjunctiva.

Infection of animals by the alimentary route is not always easy as the gastric juice tends to kill the vegetative forms of *Toxoplasma*. The pseudocysts are more resistant and the feeding of tissues containing them has proved to be the easiest way of achieving

it. Neither is it always easy to reproduce the disease in animals, and it has been found that if dogs are inoculated with the parasite, even with highly virulent strains, only the younger pups develop the acute form of the disease, the older dogs remaining quite free from all signs of infection. Recently dogs have been suggested as a probable source of human infection, as not only has acute toxoplasmosis occurred in the owners of dogs harbouring *T. gondii* but neutralising antibodies have been demonstrated in the blood of more than one-third of the owners of dogs from whom the parasite has been recovered. Whatever significance may be attached to such findings, it should be remembered that as there is usually a very close association between dogs and their owners, it is equally probable that both could have been infected simultaneously, from the same source.

Until the life cycle of *T. gondii* is known, it seems unlikely that the many problems concerning the epidemiology of toxoplasmosis will be solved. Of the many prevailing surmises on the mode of entry of the parasite into the human body, the majority of those who have studied the disease consider the three following routes the most probable:

- (i) the gastro-intestinal tract, following the ingestion of infected food;
- (ii) the respiratory tract, by inhalation of droplets containing the parasite;
- (iii) the skin and blood-stream, following the bite of an infected arthropod.

It is not yet known whether the vegetative forms of *Toxoplasma* are as vulnerable to human gastric juice as they are to that of experimental animals; nor is it known how resistant the pseudocysts are to storage, desiccation, cold or heat. Since they occur quite frequently in the muscles of animals used as food, the eating of raw or insufficiently cooked meat would seem a likely source of infection. The pseudocysts have also been found in the ovaries of hens; it is therefore possible that eggs could convey the infection. Recently toxoplasmosis has been recognised in cattle and the disease has been transmitted to calves, both congenitally and in the milk. In nearly all rural areas in Great Britain unpasteurised milk is the only form available, and this could well provide another source of infection should the disease become common in cattle.

It has already been mentioned that *Toxoplasma* are present in the bronchioles and probably in the sputum of human cases of toxoplasmosis with pneumonitis, and this is true of domestic animals with clinical evidence of the disease. Moreover, respiratory symptoms are a much more prominent feature of the disease in most animals than they are in man, and thus those looking after such sick animals might well become infected by the inhalation of infected droplets, and also possibly through the conjunctiva, since animals have been infected by this route.

Apart from the bites of infected insects, infection *via* the skin is also possible through the handling of infected tissues as it is known that *Toxoplasma* can penetrate closely shaved skin and it is therefore not improbable that some human infections may be caused by the parasite entering through cracks and small abrasions in the skin. This would certainly explain the increased proportion of positive serological reactions that has already been observed, in veterinary surgeons, slaughterhouse workers and in particular in those handling rabbits.

**Pathology.**—Following infection, the parasites are distributed throughout the body by the blood-stream and become established in the cells of the reticulo-endothelial system, and also in the parenchymal cells. Localisation occurs in many organs, more often in the brain, lung, liver or spleen, parasites often being found also in the kidney, suprarenal glands, bone marrow and lymph nodes. Muscle fibres are also invaded, in particular those of the heart, as well as the skeletal muscles. They may also be found within phagocytic cells and living free in the intracellular fluids of the affected organs.

The typical lesions are small focal areas of necrosis surrounded by a zone of

inflammation containing lymphocytes, mononuclear and plasma cells. Hypertrophied cells distended with parasites, the so-called pseudocysts, are often seen. Serous exudates are commonly found in the various body cavities.

In congenital cases lesions predominate in the brain, spinal cord, retina and choroid. Inflammation often extends to the ependyma, causing ventricular block and hydrocephalus. As well as the typical necrotic foci, minute granulomata are also found in the brain, which calcify if the affected infant survives long enough. The lesions in the central nervous system are not very marked, and often sections must be searched with the greatest diligence before they are seen.

In the acquired adult infections, which usually pass unnoticed, the lesions are often found accidentally. Rarely there is a widespread dissemination of the parasite with lesions throughout the body, though more often the predominant feature is an interstitial pneumonitis with thickening of the alveolar walls, and infiltrations of giant and plasma cells. There may also be scattered areas of purulent bronchiolitis. Inflammatory and necrotic areas are also quite frequently found in the liver, spleen and heart muscle, and encephalitis has occurred in several adult cases, though it is seldom as predominant a feature as in congenital infections, or in the acquired infections of children.

**Clinical Features.**—As knowledge of toxoplasmosis increases, and as more clinical reports become available, so does it appear that the sharply demarcated clinical syndromes that were described in the earlier accounts of the disease, do not in reality exist; apart from the fairly clear-cut distinction between congenital and acquired infections.

Whilst it is still true that there is a preponderance of certain clinical features in children suffering from toxoplasmosis, with others appearing with greater frequency in adults, there no longer seem to be any clinical manifestations of acquired toxoplasmosis that are sufficiently exclusive to one or other age group, to justify the old subdivision into acquired infections—in children; and acquired infections in adults.

### 1. CONGENITAL TOXOPLASMOSIS

Acute infections with widespread dissemination of the parasites and necrotic lesions in many organs, in particular the lungs, the heart, liver, spleen, kidney, suprarenal glands and lymphatic glands have been described, but occur very infrequently in congenital toxoplasmosis. Subacute infection is the common form, with predominating neurological symptoms which may be noted at birth or shortly afterwards. If the foetus is infected very early in pregnancy, the disease will reach an advanced stage *in utero*, and cases have been recorded where the pregnancy having continued to term was followed by an obstructed labour owing to the development of hydrocephalus in the foetus.

In the typical subacute congenital infection, the symptoms and signs may be subdivided into :

- (i) those due to the presence of parasites within the body; these may be called primary symptoms and signs;
- (ii) those secondary to the principal lesions caused by the parasite, namely encephalomyelitis and choroidoretinitis.

The common primary signs are fever, with a fluctuating temperature which may at times be subnormal; jaundice, which has been described in about one-third of all congenital cases; purpura, which occurs infrequently, and a maculo-papular rash, which is extremely rare. Anæmia and leucocytosis, with an absolute increase in monocytes and lymphocytes, are found in about one-half of all cases, and the liver and spleen are not infrequently enlarged.

The signs secondary to encephalomyelitis most frequently found are muscular twitchings and convulsions; stiffness of the neck, paraplegia, respiratory weakness and cyanosis, which at times may be due to an interstitial pneumonitis; vomiting and diarrhoea. Hydrocephalus develops in the majority of infected infants and rapid enlargement of the head may occur. At times when there is early and extensive cerebral damage microcephaly may be found. The cerebral lesions become calcified if the infant survives long enough and may later give rise to Jacksonian convulsions, and the majority of infants who survive for a number of years are nearly always mentally deficient.

The ocular findings most frequently include microphthalmia, the small eyes being in striking contrast to the enlarged head; nystagmus, which may result either from poor fixation due to choroidoretinitis or from the lesions in the central nervous system; vitreous opacities and choroidoretinitis. The lesions are nearly always bilateral and cause blindness or very severe impairment of vision in those infants who survive. The majority of infants, however, die within the first few weeks of life.

## 2. ACQUIRED TOXOPLASMOSIS

(i) *Cerebrospinal*.—In the earlier accounts of toxoplasmosis this form of the disease was usually considered to be not only the invariable manifestation of infection in children, but also to be confined solely to them. Meningo-encephalitis has, in recent years, been reported many times in adults with the disease, but it is seldom the initial feature of the attack, usually occurring as a complication of the exanthematous form towards the end of the first or second week of the illness, not infrequently after the acute stage has subsided and recovery appears to have commenced.

The cerebrospinal form is probably still found more frequently in children, in whom it tends to be the predominant feature of the illness. The onset is marked by fever, very severe headache, vomiting and delirium. Convulsions often occur a day or two later and the picture presented may suggest a brain tumour. Deafness is often found, and very occasionally choroidoretinitis has been recorded, but it is not a constant feature as in the congenital infections. The attacks are frequently severe and often rapidly fatal, with death following within a few days of the onset. Some infections run a more chronic course, but not necessarily with a more favourable outcome, since death may occur several weeks after the commencement of the illness. Complete recovery is, however, by no means uncommon, without the development of any sequelæ, even when the attack has been exceedingly severe.

(ii) *Lymphatic*.—Some of the earlier accounts of toxoplasmosis mentioned that a generalised enlargement of lymphatic glands was occasionally observed, but it is only in recent years that the lymphatic form has been recognised as a clinical type that occurs without any of the other manifestations of the disease. It has been stated quite recently that probably the commonest manifestation of acquired toxoplasmosis in man yet known is a lymphadenitis resembling glandular fever. The total number of cases of this form of infection reported to date does not yet seem large enough to confirm the above statement. Although the lymphatic form is not usually described as occurring predominantly in children, nearly all the recorded cases have been found between the ages of 5 and 15 years.

As with most infectious illnesses, there is a fairly wide range in the severity of the attack and there seems to be no practical advantage in adopting the classification which divides this form into three main clinical groups since they do not appear to differ except in severity.

A proportion of these cases have a sudden febrile onset, often with a rigor, and fatigue is a common premonitory symptom which precedes the onset by several days. The fever usually rises rapidly to about 104° F. and is frequently accompanied by catarrhal symptoms, cough, headache and pain in the back. At times the throat is

sore and there may be abdominal discomfort and diarrhoea. These symptoms and the fever nearly always precede the glandular enlargement and it may be a week or more before the enlarged glands are first observed. The fever usually last for 2 to 3 weeks, occasionally for a few days only whilst it has at times, in adult infections, been prolonged for 6 to 7 weeks, with a high initial fever of about 105° F., slowly subsiding to about 102° F. some ten days from the onset, after which it may fluctuate between 100° F. and 101° F. for 2 to 3 weeks before slowly returning to normal. Although there are no complications, and recovery invariably follows, the febrile cases often require a prolonged convalescence, fatigue being a very prominent feature for 3 or 4 months following an attack.

A large number of cases are afebrile and free from any symptoms apart from, at times, some initial tenderness in the region of the enlarged glands; the general health remains unaffected by the infection. Others remain unaware even of the enlarged glands which are found during some routine examination.

The characteristic feature of this form of toxoplasmosis whatever degree of severity it may assume, is enlargement of one or more groups of lymphatic glands. Those most frequently affected are the cervical, suboccipital, axillary and inguinal groups. A radiograph of the chest may also reveal enlargement of the hilar glands. Enlargement of the cervical glands is fairly constant and they are nearly always the first glands to become affected, other groups becoming enlarged after an interval of several days or even 1 to 2 weeks. The glands are usually firm, discrete and vary in size from that of a hazelnut to that of a walnut. They are usually painless, though there may be some initial tenderness during the first week or two of the illness. There is no inflammation of the skin overlying the glands and suppuration does not occur.

Another very characteristic feature of all cases whether febrile or afebrile is the persistence of the glandular enlargement; enlarged lymph nodes usually can be found 6 to 9 months after the onset of the attack.

(iii) *Exanthematous*.—Although many clinical forms have been described in adults, the most typical is an acute febrile illness of sudden onset, sometimes marked by rigors, soon followed by the appearance of a generalised maculo-papular rash which is absent from the palms of the hands and the soles of the feet, and which closely resembles the rash of typhus or Rocky Mountain spotted fever. There may be a disseminated myositis giving rise to severe aching pain in the muscles, or at times to myocarditis when the heart muscle is involved. The outstanding feature, however, is a diffuse, interstitial pneumonitis resembling an atypical virus pneumonia, which frequently runs a rapid course with severe dyspnoea, cyanosis and respiratory failure. Enlargement of the liver and spleen will be found in a few cases and encephalitis has recently been a feature of several acute cases in adults.

**Diagnosis.**—*Clinical Diagnosis*.—Even presumptive evidence of *Toxoplasma* infection is rarely obtainable on clinical findings alone, except in infants. A combination of convulsions, hydrocephalus or microcephaly, choroidoretinitis and calcified areas in the brain, seen in a radiograph, strongly suggests toxoplasmosis when found in infancy, and in older children a similar picture, together with blindness or serious impairment of vision and mental deficiency makes a similar diagnosis equally probable. In adults clinical diagnosis is extremely difficult and it is more likely to be considered under the differential diagnosis of an unidentified infection than as a probable diagnosis by itself.

**Laboratory findings.**—The usual routine laboratory investigations give little help in toxoplasmosis. (i) *Blood*.—Anæmia of moderate degree is usual, particularly in infants, though the hæmoglobin is seldom less than 12.3 g. or the red cell count below 4 million. The leucocytes are usually slightly increased in numbers, from 9000 to 12,000 being a common finding with a considerable increase in lymphocytes and monocytes in many cases, the increase in monocytes being of lesser degree but

much more constant. In several proved cases eosinophils have been raised to from 14 to 20 per cent. of the differential count.

(i) *Cerebrospinal fluid*.—This is often xanthochromic in cases with encephalomyelitis. Protein: usually considerably increased, the increase being relatively greater than that of the cells; Sugar: normal in amount or slightly decreased; Cells: leucocytes are often present in large numbers, with a very considerable range, an average or usual figure being around 500 per c.mm., though counts of 60 and 1600 are often recorded; erythrocytes are usually present but in lesser numbers.

*Definitive Diagnosis*.—The definitive diagnosis of toxoplasmosis by the direct isolation of *T. gondii* from the patient, is frequently not possible and therefore indirect methods are also employed, and provided that a full range of investigations is carried out, with consistent findings, a diagnosis of toxoplasmosis may still be established with reasonable certainty.

(i) *Morphological Identification of Toxoplasma*.—During the acute stage of the infection the parasite may sometimes be found in stained smears of bone marrow, in material obtained by splenic puncture or in the centrifuged deposits of exudates, cerebrospinal and ventricular fluids. Fresh cover-slip preparations should also be examined. Smears should likewise be made from a portion of any tissues removed at biopsy or autopsy, and these should be stained with Giemsa; the other portions should be fixed, and thin sections made, which should be stained with hæmatoxylin and eosin, and then very carefully examined with an oil immersion lens. The parasites in the pseudocyst form are those most easily recognised after a little experience.

(ii) *Biological Identification of Toxoplasma*.—Material obtained from a suspected case of toxoplasmosis should be inoculated into laboratory animals, which must be free from naturally occurring infection in themselves. Mice, hamsters and guinea pigs are the most satisfactory animals, and at least six mice and two guinea pigs must be used before any reliance can be placed on the test. Similar material to that used for making stained smears should be injected intracerebrally into the mice and intraperitoneally into the guinea pigs. The animals should be watched for signs of illness; if after a month all have remained well, passage to another group of animals should be undertaken by the inoculation of tissues from one-half of the first group. Where illness develops, exudates should be carefully examined, and if *Toxoplasma* are not found, part of these fluids should be inoculated into other animals. Smears should be made, and carefully examined, from the brain, lung, liver, spleen and the peritoneal lining of any animals that die. The parasite may be found after the primary inoculation and it is frequently isolated after the first passage. For practical purposes not more than three passages should be performed since it is quite exceptional for the parasite to be recovered if the first three passages have proved to be fruitless.

Direct demonstration of the parasites has only been possible in about one-half of the total number of human cases so far described.

*Indirect Methods of Diagnosis*.—(i) *Complement-Fixation Test*.—An antigen derived from chick-embryo cultures should be employed and the test serum should be examined within 24 hours of taking the blood, as complement-fixing activity may develop spontaneously after a longer period. Complement-fixing antibodies develop 3 to 4 weeks after infection occurs and may persist for several years in fairly high titre, although they often disappear during convalescence. Some 10 per cent. of healthy adults give a positive result with this test but a titre of over 1:8 suggests a recent infection.

(ii) *Neutralising-Antibody Test*.—Infection with *T. gondii* leads to the formation of antibodies in the blood which may persist for many years after recovery. They may be demonstrated by their ability to prevent infection of the chick-embryo with *Toxoplasma*, or the development of skin reactions in the rabbit. Although all human

sera produce an erythema with œdema of the rabbit's skin within 24 hours of injection, this usually fades after 4 days. If, however, any *Toxoplasma* are present and are not neutralised by antibody, a typical lesion will develop around the site of the injection after 3 or 4 days, becoming fully developed about the eighth day. The test is performed by injecting intracutaneously mixtures of the patient's serum with living *Toxoplasma*, obtained from cultures, in a shaved area on the back of a rabbit. Several dilutions of the *Toxoplasma* suspension are made in order to obtain the neutralising titre of the serum. This test is not very reliable and it should not be used unless other tests are also performed.

(iii) *Toxoplasmin Skin Test*.—The toxoplasmin is prepared from a special strain of *Toxoplasma* which are killed by irradiation from a germicidal electric lamp. Intra-dermal injections of suitable dilutions of toxoplasmin and a control antigen are made in the skin of the patient, and the area is observed after 48 and 72 hours. A positive reaction, indicating infection by *Toxoplasma*, consists of an area of erythema and induration exceeding 10 mm., present after 48 hours, with an absence of reaction in the area of the control. The test is more reliable than the neutralising antibody test, but, like the former, it does not indicate the state of activity of the disease, positive reactions being given by from 10 to 20 per cent. of apparently healthy people.

(iv) *Methylene Blue Dye Test*.—If films, made from a suspension of parasites and normal serum, are stained with alkaline methylene blue, the parasites will appear as rounded, deeply stained bodies; if, however, the serum contains specific antibodies together with an "accessory factor", some modification takes place in the cytoplasm of the parasite so that they no longer accept the stain. Until quite recently great reliance was placed on this test, but it is now known that it is by no means specific for *Toxoplasma*, a positive result being obtained also with *Sarcocystis*, *Trichomonas vaginalis* and *Trypanosoma lewisi* and probably other parasites. These findings do not necessarily invalidate the dye test, though the interpretation of the test when low titres are obtained is not easy. It is probably wise to insist that for a diagnosis of active toxoplasmosis to be justifiable, not only must the dye test and the complement fixation tests be positive, but their respective titres should be not less than 1:128 and 1:8. In practice it will be found that the complement fixation test is nearly always positive with a dye test titre of 1:128.

*Differential Diagnosis*.—(i) In infants. When jaundice is present and the liver and spleen are enlarged, it must be distinguished from erythroblastosis foetalis. Birth injury, bacterial meningitis, foetal infection with many viral diseases may also present somewhat similar features.

(ii) In older children, with neurological abnormalities present it must be distinguished from tuberculous sclerosis; cerebral angiomas; also from brain tumours.

(iii) In adults with acute infections, typhus, Rocky Mountain spotted fever and atypical pneumonia are the most likely causes of confusion. Toxoplasmosis should also be considered when myocardial disease is found where the cause remains unexplained. Pseudocysts occur frequently in the skeletal muscles and have at times been mistaken for sarcosporidia.

(iv) The lymphatic form will almost certainly be mistaken for glandular fever in the majority of cases, and it seems highly probable that if this form of toxoplasmosis is much more common than is generally realised, many of the "clinical diagnoses" of glandular fever where the blood picture is atypical and the Paul-Bunnell test negative, may in fact be toxoplasmosis, since of the total number of such cases in any year, a very small proportion indeed will even arouse a suspicion of toxoplasmosis. It is certainly true that in many an outbreak of fever accompanied by glandular enlargement, giving a clinical picture that suggests glandular fever, laboratory confirmation may be obtained for only some 10 to 20 per cent. Enlarged glands may frequently be present in such cases 5 to 6 months later.

The persistence of the glandular enlargement may also at times arouse suspicion of Hodgkin's disease.

**Prognosis.**—The lymphatic form of toxoplasmosis runs a benign course, recovery being apparently invariable, and the prognosis is therefore excellent. Of the other forms of toxoplasmosis the great majority of recorded cases have ended fatally to date, but until the true incidence of the disease is known with accuracy, the case mortality will probably continue to be disproportionately high, since the majority of diagnoses will be amongst the most severe infections, with a large number obtained after post-mortem examination. Until a few years ago, recovery was the exception, but an increasing proportion of recoveries from the clinical forms of toxoplasmosis have more recently been recorded.

The congenitally acquired infections usually have a fatal termination either within the first few months of life, or in early childhood with the few years of survival marred by greatly impaired vision or blindness, and retarded mental development. Acute toxoplasmosis in children, marked by involvement of the central nervous system have usually had a fatal termination, though there have been several reports of complete recovery, no sequelæ being apparent. In adults a greater number of recoveries have been recorded, the outlook being more favourable when the respiratory symptoms predominate, even though the mortality with this form remains high. Encephalitis was considered unusual in adults a few years ago; during the last 5 years it has been a feature of a considerable proportion of the diagnosed infections in adults, with a fatal termination in about one-half. Laboratory infections have not been numerous but they have been exceptionally severe, nearly all of them being fatal.

In recent years evidence based on serological tests has been accumulating, though the findings cannot be accepted without reserve, since, apart from many technical difficulties making the tests often unreliable, the dye test, which was considered the most satisfactory, has recently been shown to give positive reactions with a number of other protozoa. Despite these objections, it appears that in the latent or sub-clinical form toxoplasmosis is common, and that the clinically recognisable infections are extremely rare. Thus it is probably true to say that whilst the case mortality from the disease toxoplasmosis remains very high, the mortality following infection by *Toxoplasma* is extremely low.

**Treatment.**—It will be apparent from the remarks made under prognosis that no effective treatment has been available for toxoplasmosis in the past. Animal experiments have been made in which a very wide range of drugs have been tested, and whilst a number have had some effect, very few have encouraged clinical trials in human infections.

Laboratory experiments have shown that several of the sulphonamide compounds are curative if the infection is not a heavy one and the drug is administered soon after infection. By far the most active of these compounds is sulphapyrazine, which also possesses some antimalarial activity, and even when the dose is reduced to half that of the other sulphonamide compounds it is still much more effective. It may, however, have some toxic properties as it has not yet been made available commercially.

Most of the broad-spectrum antibiotics have given somewhat similar results. Of the newer ones, puromycin and tetracycline (Achromycin—Lederle) have been extensively tested in the laboratory but neither of them are considered sufficiently effective for any further trials. Further recent trials with chlortetracycline (Aureomycin) have shown that it will cure heavy infections in laboratory animals if very large doses are used, but it is doubtful if such high dosage would be tolerated in human infections.

Pyrimethamine (Daraprim), an antimalarial drug found to be suppressive in very small doses as well as an effective therapeutic agent, has very recently been reported to be curative in human toxoplasmosis. Published information is still

limited to a few reports, but it appears to be the most effective remedy at present available, particularly when combined with sulphadiazine. The effect of this combination appears to be synergistic since it has been found to be six times greater than would be expected if it was purely additive. The best results are given by a combination of 22 per cent. pyrimethamine to 78 per cent. sulphadiazine. The most effective doses of pyrimethamine are considerably higher than those normally used in practice, the lower dosage being adopted on account of the risk of toxic effects. Treatment is usually commenced with a small dose of 25 mg. daily which is increased after 3 or 4 days to 50 mg. daily. Treatment is usually continued for 10 to 14 days, the total dosage of pyrimethamine being from 500 to 700 mg. In one series of 13 cases receiving this treatment, one patient was left with a psychosis, the cause being unknown; complete recovery was recorded for the remainder. Pyrimethamine has also been tried in cases of uveitis where serological tests suggested toxoplasmosis to be a possible cause. The results so far have been rather indecisive but further trials are still in progress.
